In the rare event that a patient presents with agranulocytosis or vasculopathy suggestive of the cocaine adulterant levamisole, a special laboratory evaluation for urine levamisole by gas chromatography–mass spectrometry may be requested. The sample is ideally obtained within 48 hours after last use. 10

**MANAGEMENT**

A severely poisoned patient may be combative and unable to cooperate in assessment of vital signs. Actions taken during these first stages of the encounter are crucial (Box 149.3). Because the etiology of the patient’s condition is often unclear, the initial priority is to recognize and treat the life-threatening agitation and delirium. Patients may transiently require physical restraints for complete vital signs to be obtained and IV access to be secured. If a chest restraint is used, a mesh vest is preferred to a jacket to help limit hyperthermia. The patient should have assessment with a bedside blood glucose monitor. Immediate pharmacologic sedation with IM or IV administration of benzodiazepines may be necessary (see next section), which, in adequate doses, restores inhibitory tone to the CNS and decreases excessive sympathetic outflow to peripheral tissues. Sedation also facilitates measurement of vital signs (particularly core temperature), continuous electrocardiographic monitoring, and completion of the physical examination.

**Pharmacologic Sedation for Agitation**

Benzodiazepines are the mainstay of treatment of cocaine–induced agitation. Diazepam, lorazepam, and midazolam have all been successfully used in this setting. Diazepam can be administered intravenously in increments of 5 to 10 mg every 5 minutes in adults until sedation is achieved. Diazepam has a rapid onset of action, is easily titratable, and has active metabolites for a sustained effect. Lorazepam, 1 to 2 mg intravenously every 5 minutes is also an acceptable option. Persistently increased motor tone reflects an inadequate benzodiazepine dose, even if the patient appears sleepy. Additional doses of lorazepam or diazepam can be given, with close monitoring of the patient’s respiratory status. For an adult patient in whom IV access is not possible because of agitation, IM midazolam 10 mg can be administered to facilitate subsequent interventions. Although lorazepam also can be given intramuscularly, it may take 15 minutes to reach peak sedation; and repeated doses given at more frequent intervals may accumulate, causing oversedation and respiratory depression. Because cocaine agitation can be indistinguishable or coexist with alcohol intoxication, the presence of alcohol can have synergistic depressant effects on the respiratory centers. In all patients, titration of the benzodiazepine is important, allowing the clinician to observe the effects of one dose (usually 5 minutes) before an additional dose is given. After sedation is achieved, the patient is closely observed to ensure that the patient’s respiratory status is stable when peak sedation effect is reached.

Benzodiazepines also treat the choreothetoid movements of crack dancing. Most cocaine toxic patients have salt and water depletion and require vigorous IV crystalloid replacement. If the...
cause of delirium is unclear, careful attention to the patient’s respiratory status avoids the respiratory depression caused by excessive benzodiazepine administration in the presence of other sedative-hypnotic agents, such as ethanol.

The vast majority of patients with cocaine-induced agitation respond clinically to adequate doses of benzodiazepines. Butyrophenone antipsychotic agents (such as, haloperidol and droperidol) are rapidly effective and generally safe for drug-induced psychosis or agitation states from sympathomimetic agents, including cocaine, amphetamines, and PCP when used in patients with normal vital signs (also discussed in Chapters 140 and 150). Haloperidol, 2 to 5 mg IM, may be repeated every 20 to 30 minutes with consideration of other agents after a total of 10 mg. Although not approved for IV use, this route is widely used and should only be considered in the psychotic patient with normal vital signs with close cardiac monitoring in 5-mg doses with a maximum dose of 15 mg. The sedative dose for droperidol is 2.5 to 5 mg IM. Droperidol has a box warning from the U.S. Food and Drug Administration (FDA) for QT prolongation and potentially torsade de points. However, most reported cases of butyrophenone-induced dysrhythmias have been in individuals receiving large doses for prolonged periods, such as hours to days, or in elderly populations (older than 60 years). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when sedation is required. For these reasons, the butyrophenones remain effective agents for treatment of drug-induced agitation in carefully selected patients.

Hyperthermia

Cocaine-induced hyperthermia must be treated with rapid cooling (Box 149.4). Patients who sustain elevated core temperatures above 106°F (41°C) for more than 20 minutes are likely to subsequently have fatal multisystem organ failure, which is often heralded by disseminated intravascular coagulation. Patients should have continuous monitoring of core temperature with a rectal probe. Heat generated by agitation and increased muscle tone can be terminated by adequate use of benzodiazepines, as described earlier, with neuromuscular paralysis and intubation as required. Although cocaine use or intoxication, per se, is not a contraindication to use of succinylcholine for intubation, we recommend use of rocuronium, 1 mg/kg, when possible. Succinylcholine shares metabolism through plasma cholinesterase with cocaine, which may nominally prolong the effects of both drugs, succinylcholine also may precipitate hyperkalemia if rhabdomyolysis, which often occurs with cocaine use, is present. It is crucial to reduce core temperature to 102°F (38.8°C) as soon as clinically possible, ideally within 20 minutes or less. Cooling blankets are insufficient. Ice water submersion in a portable tub is preferred when available; although some favor wet sheets with large fans. These patients require continuous temperature monitoring and fluid resuscitation as judged by standard measures. Invasive cooling techniques are often too delayed and inadequate against the vasoconstrictive effects of cocaine and other adrenergic agents.

**Acute Hypertensive Emergencies**

The goal in acute hypertensive emergencies is to promptly reverse the vasoconstriction of norepinephrine at peripheral adrenergic receptors. Benzodiazepines restore the CNS inhibitory tone on the peripheral nervous system and are first line treatment, as outlined earlier for agitation. When ECG evidence of myocardial ischemia is present, IV nitroglycerin can be used, but control of the blood pressure by phentolamine, which we consider the drug of choice, usually will resolve the issue. Phentolamine, a direct alpha-adrenergic antagonist, can be titrated slowly by repeated IV doses of 1 mg every 3 minutes with blood pressure monitoring. If adequate reduction in therapy by at least two-thirds of mean arterial pressure is not achieved after two doses, phentolamine dose can be escalated by 1 mg every 3 minutes up to 5 mg/dose until adequate vasomotor control is achieved. Phentolamine effect will last roughly 45 minutes. Supplies of phentolamine in the United States have been subject to shortage. If phentolamine is not available, other antihypertensives that can be used include hydralazine, nitroglycerin, and short-acting IV calcium channel antagonists like nicardipine or clevidipine (see Chapter 74). In contrast to chronic hypertension, individuals with acute cocaine hypertension often have a normal blood pressure in the absence of the drug, and unless the patient’s history suggests otherwise, a normal systolic and diastolic blood pressure should be the endpoint of therapy. Shorter acting antihypertensive infusions offer an advantage in that they can be readily discontinued as the cocaine is metabolized and the vasomotor effect subsides.

Historically, it has been theorized that beta-adrenergic antagonists (beta blockers [BB]) may cause paradoxical hypertension with acute cocaine toxicity and should be avoided due to concerns of unopposed alpha-receptor activity, resulting in coronary artery spasm and hypertension. Furthermore, patients undergoing cardiac catheterization show decreased coronary artery diameter in the presence of cocaine and beta-adrenergic antagonists.

In two retrospective studies, beta-blocker use was not associated with clinically significant hypertension, troponin elevation, or adverse events. Despite this, we do not feel that their use provides a clinical benefit in this setting and do not recommend the routine use of beta-blocker therapy in patients presenting with cocaine-induced hypertension and chest pain.

The treatment of cocaine-induced SAH or aortic dissection differs from treatment of other causes of the same conditions. The combined use of phentolamine and beta-adrenergic antagonists may result in profound hypotension, and we therefore recommend initial administration of phentolamine only, in the manner described earlier, with close monitoring for sudden alterations in blood pressure. If phentolamine is unavailable, a short acting antihypertensive infusion can be used (eg, nitroglycerin, nicardipine, or clevidipine) combined with pain control and benzodiazepines to diminish adrenergic output.

**Box 149.4**

Management of Stimulant-Induced Hyperthermia

**COOLING**

Early identification of elevated core temperature
Large-bore IV access with rapid infusion of crystalloid
Sedation and muscle relaxation with benzodiazepines
Rapid cooling within 20 minutes*
Paralysis and intubation if necessary

**MONITORING AND DIAGNOSTICS**

Urine output via Foley catheterization
Laboratory analysis for organ function
Serum chemistries, creatinine, CK
Liver function
PT, PTT, fibrin split products
Bacterial cultures
Urinalysis for myoglobinuria
Neuroimaging if etiology unclear

*Ideally with ice water immersion.

1Consider lumbar puncture or antibiotic therapy, especially in injection drug users. CK, Creatine kinase; IV, intravenous; PT, prothrombin time; PTT, partial thromboplastin time.
Dysrhythmias

Dysrhythmias from cocaine may be atrial or ventricular. Atrial fibrillation and supraventricular tachycardias are likely to be due to sympathetic stimulation and often respond to benzodiazepines. Calcium channel blockers (e.g., diltiazem) can be used if rapid atrial rhythms fail to respond to sedation, cooling, and volume resuscitation.

Important considerations in the differential diagnosis of a wide-complex tachycardia include hyperkalemia, direct sodium channel blockade (cyclic antidepressants and cocaine), and ventricular ischemia. In cocaine body packers or patients presenting with cocaine-induced adrenergic toxidrome, abrupt development of a wide-complex tachycardia with a pulse should be treated with empirical sodium bicarbonate, 1 to 2 mEq/kg IV bolus, with closely recorded cardiac monitoring to observe for QRS narrowing.21 If the patient does not respond with both QRS narrowing and hemodynamic stabilization, lipid emulsion therapy may be attempted in consultation with a medical toxicologist, but there is no evidence to support its use.21

As with any dysrhythmia, fluid and electrolytes should be assessed and corrected as indicated. Close monitoring is required for patients with a Brugada-type conduction pattern. Data regarding the ideal antidysrhythmic agent in this setting are limited.

Cocaine-Related Chest Pain

The causes of cocaine-related chest pain are diverse (Box 149.5), including aspirated foreign bodies or pneumothorax or pneumomediastinum from inhalational barotrauma. Fever and shortness of breath should prompt consideration of pneumonia, pulmonary infarction, or endocarditis with septic pulmonary emboli in IV drug abuse.

Cocaine acutely induces coronary vasoconstriction while increasing myocardial oxygen demand. Platelet aggregation is enhanced through thrombogenic and antifibrinolytic pathways. These cumulative effects can result in coronary insufficiency. Cigarette smoking acutely exacerbates these conditions. Chronic cocaine use may accelerate atherogenesis and induce left ventricular hypertrophy. All of these factors contribute to myocardial ischemia or infarction. Of nonfatal myocardial infarctions in patients aged 18 to 45 years, 25% are attributed to cocaine, even after adjustment of other known cardiac risk factors.

Identification of a patient with a cocaine-related coronary syndrome is difficult. Patients may present hours to days after use, possibly because of vasoactive metabolites. The patient may deny drug use and have atypical chest pain. Almost one-third of cocaine-using patients with elevated serum enzymes have pleuritic chest pain. There are no clear predictors for patients at risk because the patient's age, route of drug use, time to presentation, and preexisting risk factors for coronary artery disease are inadequate to identify patients sustaining myocardial infarction. In the setting of cocaine-related chest pain, risk stratification by thrombolysis in myocardial infarction (TIMI) score may not adequately identify patients at risk for 30-day adverse outcomes. However, in one study, cocaine history alone in low-risk, asymptomatic patients assessed by coronary CTA is generally not associated with increased risk of coronary artery disease. Patients with positive serum enzymes for myocardial infarction often have significant angiographic stenosis. Of patients without positive serum markers, 18% still have significant disease by angiography. Other predictors of significant disease in this group included elevated cholesterol concentration and prior diagnosis of coronary disease or myocardial infarction. Patients with previous coronary stent placement are at a high risk of thrombosis with cocaine use.

As for most complications of cocaine use, benzodiazepines decrease myocardial oxygen demand by limiting peripheral stimulation and should be given early to patients presenting with cocaine-induced chest pain, especially when signs of adrenergic excess are present. Aspirin and nitrates should be administered as for any case of suspected ischemic chest pain. In patients meeting electrocardiographic criteria for myocardial infarction with persistent chest pain and hypertension and a clear history of acute cocaine intoxication, coronary vasodilation with IV phentolamine (1 mg) can be given slowly during 3 minutes if available. This dose can be repeated, if needed, as long as the patient's blood pressure remains stable. Morphine sulfate can be used to treat pain. Patients with persistent chest pain and ST segments strongly suggestive of myocardial infarction can be considered for percutaneous intervention or thrombolytic therapy, assuming there are no contraindications, such as uncontrolled severe hypertension.1

In contrast to non–cocaine-induced myocardial ischemia or infarction, beta-adrenergic antagonists, including labetalol, are generally not recommended during acute cocaine toxicity because coronary vasoconstriction may worsen.

In patients with cocaine-related coronary syndromes who are not acutely toxic, alpha-adrenergic vasoactive metabolites may be responsible. Outcomes of uncomplicated chest pain due to cocaine are very good. Current guidelines for care of the patient with an acute coronary syndrome that is unrelated to cocaine do not recommend immediate administration of beta-adrenergic antagonists, but rather within the first 24 hours.22 As such patients with known or suspected cocaine-related myocardial infarction with or with ST segment elevation, there is little role for beta-adrenergic antagonists in the ED and we do not recommend their routine use.16,22 Such patients warrant a further evaluations of coexisting atherosclerotic heart disease and clinical reevaluation prior to consideration of this therapy. Administration of beta-adrenergic antagonists on discharge is controversial, especially if cocaine use is likely to continue, and we advise against this practice.22

Heparin can be given, but fibrinolytic therapy is not well studied. Some mechanisms of cocaine-induced myocardial infarction would be expected to respond to fibrinolytic agents. Patients failing to respond to treatment with nitrates and phenolamine who have known coronary artery disease or a previous ECG confirming new ST segment elevations are candidates for cardiac catheterization or fibrinolysis if necessary. The same contraindications apply for non–cocaine-induced myocardial infarction. Nuclear imaging studies also may provide more diagnostic information.

information, but their use is best considered in consultation with cardiology. Patients presenting with chest pain after cocaine use and an ECG with definitive or new ST elevations should have prompt evaluation by a cardiologist for potential intervention when such services are available.

Antiplatelet and glycoprotein IIb/IIIa inhibitors and calcium channel antagonists seem to be of benefit to some patients with myocardial infarction or ischemia of atherosclerotic origin. Theoretically, these agents may counter some of the platelet aggregation enhanced by cocaine, but data investigating their use are lacking.

Patients with cocaine-related chest pain without other risk factors who have normal ECGs and cardiac enzymes are at low risk for myocardial infarction. The role of provocative testing in these patients is not well established.

In summary, cocaine-induced coronary ischemia is managed with benzodiazepines, nitrates and vasodilators, preferably phen tolamine. As with non-cocaine using patients presenting with acute ischemic chest pain, we recommend use of aspirin, heparin, antiplatelet agents, and calcium channel blockers in conjunction with interventional therapy as indicated.

Interventions to cease cocaine use are warranted. For patients with documented coronary artery disease, cessation of cocaine use is imperative. Cocaine users presenting with chest pain who subsequently continue cocaine use after ED discharge were more likely to have recurrent ED visits than were those who stopped subsequent use.

**Cocaine Body Packers**

Before crossing international borders, “body packers” ingest cocaine that has been wrapped tightly into condoms or other latex products and sometimes coated in wax. Each packet can contain approximately 10 g of cocaine, and packers may swallow as many as 150 packets. On arrival at the patient’s destination, a cathartic is often taken to stimulate gastrointestinal passage of the contraband for subsequent delivery and distribution. Body packers are likely to know the exact number of packets they ingested but may be reluctant to share that information.

A body packer may present without symptoms to the ED. The patient should be placed immediately on continuous cardiac monitoring, with large-bore IV access. Diagnosis is made by history. An abdominal radiograph may confirm foreign bodies but cannot be used to count packets, because plain radiographs have limited sensitivity in detecting an isolated or small number of packets. When uncertainty persists, a CT scan or contrast study is warranted.

Body packing also is used to transport heroin and other illicit substance. Although heroin body packing rarely requires surgical intervention, an asymptomatic patient may refuse to identify the packet’s contents. A urine toxicology screen may be useful because small quantities of drug may be ingested in swallowing of the contraband. Rupture of a single cocaine packet can result in death, because each packet contains almost 10 times the lethal dose. Accordingly, cocaine body packers with retained packets should be admitted to a monitored setting with a plan to facilitate removal of the packets by whole bowel irrigation.

Surgery should be consulted, and the operating room should be prepared in advance in the event that the patient develops acute toxicity. We recommend emergency surgical removal of all packets for patients with mechanical bowel obstruction or a leaking packet with symptoms suggesting a leaking packet. Because of the large quantity of pure drug in one packet, patients with a ruptured or leaking packets are likely to die without prompt intervention. When evidence of cocaine toxicity is manifested, rapid surgical intervention may be the only way to save these patients. Benzodiazepines, neuromuscular blockade, or sodium bicarbonate administration (for wide-complex tachycardia) may be required preoperatively as described earlier for treatment of acute cocaine toxicity.

Because leaking of pure cocaine from packets is potentially lethal, we recommend whole-bowel irrigation with polyethylene glycol solution to facilitate gastrointestinal passage of the packets and preoperatively cleanse the bowel in the event of emergent surgery is required. Subsequent CT scans or contrast studies may be required to evaluate for remaining packets. However, these radiographic studies may fail to detect isolated packets that contain potentially fatal quantities of cocaine. Patients stating that they swallowed a larger number of packets than are passed or who refuse to reveal the number ingested should have continued bowel irrigation, observation, and repeated studies. Endoscopic retrieval is generally discouraged because of concern for packet rupture during the procedure, but it has been done on occasion.

All packets passed in the stool, through endoscopic procedures, or in the operating room should be counted carefully and promptly given to law enforcement officials. When law enforcement is not yet involved, hospital legal counsel or risk management and the hospital ethics committee may be helpful in determining the disposition of the packets and ultimately of the patient when he or she is medically cleared.

**Body Stuffers**

A “body stuffer” is an individual who attempts to conceal evidence of cocaine possession by internally concealing the drug while being pursued by law enforcement officials. This can be most commonly through ingestions, but it may also involve vaginal or anal concealment. These are usually unplanned events with generally small quantities of drug that were initially intended for personal use. The drugs are often swallowed in poorly sealed vials or glassine packets that may not be evident on radiographs. In general, patients ingest nonlethal doses and are asymptomatic. For cooperative, asymptomatic oral body stuffers, the role of gastric decontamination is not well studied. In this setting, if presenting soon after ingestion, we recommend administration of oral activated charcoal to adsorb any potential leaking cocaine from the packets in the GI tract.

Monitoring, as described earlier with body packers, should be performed if the quantity ingested is of concern or if signs of toxicity develop. Due to lower doses and less potential lethality, the vast majority of body stuffers will not require whole bowel irrigation therapy as do body packers. Body stuffers rarely have fatal events, and these patients usually have symptoms in the first 8 hours. Asymptomatic patients who are unwilling to disclose events or cooperate with care should have monitoring in the ED regardless of status of police custody. However, if the patient is not under arrest, they are free to decline therapy and leave the ED against medical advice if they can demonstrate clear understanding of the risks, including sudden death, of leaving with retained packets. Although the ideal period of observation is uncertain, 8 to 12 hours is reasonable with admission if the patient develops signs or symptoms of toxicity. Patients with suspected vaginal or anal concealment who are asymptomatic and without signs of toxicity who refuse a physical examination should be assessed for capacity and observed in the ED as outlined earlier. Any judicial warrants for an invasive examination against patient’s will should carefully involve risk management and hospital legal counsel, because these are forensic requests and not medically emergent in the asymptomatic patient.

**Levamisole-Related Complications**

Patients with agranulocytosis, vasculopathy, or other dermatologic manifestations require supportive care, evaluation for other potential causes, and abstinence from further levamisole exposure. Reporting to the local department of health or poison control center can help track these cases.
Acute toxic patients who need only observation or who respond quickly to sedation and do not have complications can be discharged after the acute toxicity resolves. These patients may be extremely lethargic from cathalolamine depletion, and it is best to discharge them with a responsible adult. Patients may be open to drug counseling and referral while in the ED.

Patients with chest pain (Box 149.6) who are acutely toxic and who show dynamic changes on the ECG, dysrhythmias, or congestive heart failure and patients requiring vasodilators or reperfusion should be admitted to a monitored setting or coronary care unit. These patients require further evaluation of the extent of preexisting reversible ischemia and intervention to encourage cessation of drug use.

The disposition of patients with chest pain who are not acutely toxic is less clear. Admission is warranted for patients with complications or electrocardiographic changes and patients requiring pharmacologic intervention with vasodilators. Other patients may be placed in an ED observation unit or discharged, depending on the level of concern about underlying coronary artery disease using standard screening for risk factors as with non-cocaine chest pain (see Chapters 23 and 68).

In symptomatic ED patients at low to intermediate risk of acute coronary syndrome, cocaine use is not associated with an increased likelihood of coronary disease after adjustment for age, race, sex, and other risk factors for coronary disease.26 Serious complications such as congestive heart failure and ventricular dysrhythmias typically are manifested within the first 4 hours. Young patients who present after resolution of chest pain with normal and unchanging ECGs, no dysrhythmias, and few or no risks of coronary artery disease are likely to have a good outcome. Prior studies have demonstrated that these low-to-intermediate-risk patients with cocaine-associated chest pain can be safely discharged after 9 to 12 hours of observation. The goal of a more recent study was to determine the safety of an 8-hour protocol for ruling out myocardial infarction in patients who presented with cocaine-associated chest pain. Application of an abbreviated cardiac enzyme protocol (at 0, 2, 4, and 8 hours) after presentation with continuous cardiac monitoring, resulted in the safe and rapid discharge of patients presenting to the ED with cocaine-associated chest pain.27

Body packers need to be observed until all packets have passed. Ideally, these patients have had several packet-free stools, a reliable packet count consistent with the ingestion, and a normal CT scan or contrast radiographic study. Body stuffers who receive activated charcoal, have normal ECGs, and remain asymptomatic with normal vital signs after 6 to 12 hours of observation may be discharged.

### Other Stimulants

#### Amphetamines

Amphetamines enhance release of catecholamines from presynaptic nerve terminals by altering the pH of presynaptic vesicles. Amphetamines are usually taken as pills but are occasionally crushed and injected. The subsequent CNS stimulation results in sympathomimetic effects nearly identical to those from cocaine but not with the same frequency or intensity (see Box 149.1). Patients are at risk for hyperthermia, hypertensive emergencies, dysrhythmias, myocardial ischemia, and hyperkalemia associated with rhabdomyolysis.27 In contrast to cocaine, amphetamines do not block sodium channels and only minimally affect presynaptic reuptake of catecholamines. Although urine drug screens can identify amphetamines, they are of little utility in treatment of a toxic patient. The management follows the same guidelines as for cocaine (see Box 149.3), although the duration of toxicity is longer for amphetamines. Phenylethylamines, which are closely related in molecular structure to amphetamines, include the “2C” and “NBOMe” drugs named for the location of specific structural elements.29 These have powerful serotonergic, hallucinogenic effects; and patients can present with adrenergic toxicity and behavioral agitation. The brominated form (named “bromodragon”-only due to its structural similarity to a dragonfly in shape) is associated with a necrotizing angiitis that can compromise blood flow to limbs. Limb or digit pain in such patients warrants a comprehensive monitoring and evaluation for vasospasm and tissue ischemia.30

#### Methylenedioxymethamphetamine

Methylenedioxymethamphetamine (MDMA, ecstasy, XTC, Adam) is a chemically modified amphetamine originally taken orally at all-night dance parties or “raves.”31 Patients describe the euphoria allowing “closeness to others,” so it is sometimes called the love drug. The molecular structure of MDMA confers some serotonergic properties that may account for the “shimmering” (a sense of a flickering light) visual effects reported. The term Molly is often used to describe a product with a higher concentration of MDMA. Analysis of products sold as Molly often reveals substitute agents—some of which are inert and others may have adrenergic effects. User reports are, therefore, often unreliable in determining the true exposure.

Along with the usual complications of amphetamines, MDMA can precipitate a life-threatening hyponatremia. MDMA or its metabolite alter release of endogenous stores of vasopressin, which in the setting of high free water intake results in free water retention. Although the exact mechanism is not understood, patients with MDMA-induced hyponatremia have concentrated urine samples with a relatively high urine sodium concentration, similar to the SIADH. Unless seizures or other neurologic events are present, patients can be treated supportively with fluid restriction. Urine can be tested for specific gravity, and a sample should be sent to the laboratory for electrolyte analysis and osmolality. Normal saline or other crystalloids may worsen the hyponatremia, because these patients are likely to retain more free water than sodium. Their fluid intake should be restricted unless severe hypovolemia exists, and they should be treated with hypertonic saline for neurologic impairment. A newer treatment of hyponatremia includes vasopressin V2-receptor antagonists, but it has not been described for these patients. In contrast to other amphetamines, chronic MDMA use causes potentially irreversible neurologic damage to serotonergic neurons. Other MDMA variants,
such as 3,4-methylenedioxyethamphetamine (Eve), may cause similar complications.

**Methamphetamine**

Methamphetamine, known as crank and crystal meth, is a fat-soluble, smokable, designer amphetamine. Complications from methamphetamine use are similar to those from other sympathomimetics. The duration of action can be significantly longer, however, with some paranoid delusions persisting for 15 hours. The production of methamphetamines requires a variety of metal salts, and lead toxicity from inappropriately produced drug is reported. Injuries during illicit methamphetamine production or police raids include exposure to anhydrous ammonia, hydrochloric acid, sodium hydroxide, ether, and ephedrine, as well as burns and explosions.

**Ephedrine and Ephedra**

Ephedrine is another illicitly used amphetamine-like agent associated with complications of excessive sympathomimetic stimulation. Ephedra, a plant-derived product, also known as a Chinese herbal product, ma huang, has been associated with strokes and deaths in adolescent users. The FDA has banned all ephedra-containing dietary supplements.

**Khat and Methcathinone**

Khat is a stimulant agent naturally occurring in the leaves of the plant *Catha edulis*. These leaves are chewed to extract the active compounds, cathinone and methcathinone, which are stimulants with sympathomimetic effects. Management and disposition follow the same guidelines as for cocaine. Smoking of khat does not typically result in clinical effects, because the agent degrades with pyrolysis. Illicitly manufactured methcathinone is known as cat or qat. Some methcathinone users experienced an extrapyramidal syndrome associated with elevated manganese concentrations, probably resulting from an inadvertent contaminant during production or inadequate purification. The role of chelation therapy for elevated manganese concentrations is uncertain.

**Bath Salts**

Bath salts were first encountered in Japan in 2006. The ease of synthesis and modification of specific functional groups of the parent cathinone make these drugs particularly difficult to regulate. Substances are vended as “bath salts” or “plant food” and labeled “not for human consumption.” These synthetic cathinones sold unregulated over the Internet initially contained mephedrone, but their content rapidly changed to include methylone, ethylone, butylone, pyrovalerone, methylenedioxypyrovalerone (MDPV), methcathinone, and ethcathinone and their chemical variants. These substances are exploited for an adrenergic “high” but have no pharmacologically approved medical indications in the United States. Bath salts may be ingested, inhaled, or injected and can result in severe agitation, sympathomimetic effects, hyperthermia, and rhabdomyolysis. Numerous fatalities have been reported, causing the U.S. Drug Enforcement Administration (DEA) to categorize these agents illegal and as Schedule I substances. Synthetic cathinones are usually not detectable on routine urine drug screens. Treatment is similar to that of cocaine and amphetamine toxicity, including adequate dosing of benzodiazepines for agitation with diazepam, lorazepam, or butyrophenone antipsychotic agents, such as haloperidol and droperidol (see Management, Pharmacologic Sedation for Agitation section).

**KEY CONCEPTS**

- Rapid sedation with an IV benzodiazepine is the key for most symptoms from cocaine and other stimulants.
- Hyperthermia is a high-risk event, and body temperature must be reduced rapidly.
- Short-acting antihypertensive agents (such as, phentolamine, nitroglycerin, nicardipine, or clevidipine) are recommended for cocaine-induced hypertension, including in the presence of chest pain.
- Wide-complex rhythms secondary to cocaine may respond to IV sodium bicarbonate therapy.

- Cocaine body packers who develop symptoms of acute cocaine toxicity need emergent surgical intervention.
- Amphetamine symptoms and effects last longer than those produced by cocaine.
- Hyponatremia should be rapidly identified in patients with an altered mental status after use of illicit stimulants, most specifically MDMA.
- Synthetic cathinones or “bath salts” may be ingested, inhaled, or injected and can result in severe agitation, sympathomimetic effects, hyperthermia, and rhabdomyolysis. Fatalities have been reported.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
149.1. How long does a typical urine drug screen result remain positive after use of cocaine?  
A. 1 day  
B. 3 days  
C. 1 week  
D. 2 weeks  
E. 1 month  

Answer: B. Urine drug screens detect the cocaine metabolite benzoylecgonine, which is typically present in the urine for 3 days after the last use.

149.2. A 24-year-old man is seen by police to be smoking crack cocaine on a street corner. On the way to the jail, the patient reports a severe headache, so the police bring him to the emergency department (ED) for medical clearance. The patient is awake with normal mental status but continues to complain of diffuse head pain. His vital signs are blood pressure (BP), 195/99 mm Hg; heart rate (HR), 102 bpm; respiratory rate (RR), 18 rpm; and temperature, 37.2°C. His physical examination is normal. How should his headache be evaluated?  
A. Acetaminophen administration, discharge if headache resolves  
B. Blood pressure reduction, discharge if headache resolves  
C. Head computed tomography (CT) scan, discharge if normal  
D. Head CT scan, lumbar puncture if normal, discharge if both are normal  
E. No evaluation needed; cocaine is not associated with headache  

Answer: D. Cocaine is associated with subarachnoid hemorrhage (SAH). Patients complaining of a severe headache after cocaine use should receive a complete evaluation for SAH, including head CT and lumbar puncture. In addition, elevated blood pressure should be lowered while the evaluation is being performed.

149.3. What is the preferred primary method for controlling a combative patient suffering from a sympathomimetic overdose?  
A. Chlorpromazine  
B. Diazepam  
C. Droperidol  
D. Haloperidol  
E. Physical restraints  

Answer: B. Diazepam and other benzodiazepines are the best agents to sedate and establish control of an agitated patient. They cause sedation as well as decrease muscle tone, which can ameliorate hyperthermia. In addition, they can lower the acutely
increased blood pressure often seen with sympathomimetic use. In the agitated patient when intravenous (IV) access may be difficult to establish, lorazepam is more predictably absorbed than diazepam. Chlorpromazine can be given intramuscularly to provide rapid sedation, but it is associated with anticholinergic effects that may exacerbate hyperthermia. Butyrophenone agents (eg, haloperidol and droperidol) are reserved for more severe agitation and are considered secondary methods of treatment after adequate doses of benzodiazepines. Also, they may have associated dysrhythmic effects that are additive to those of cocaine. Physical restraints may be necessary initially but are not desirable, because they can also increase the risk of hyperthermia as well as increase agitation, which is associated with sudden death.

149.4. A 27-year-old woman presents with severe chest pain that began soon after use of a large amount of cocaine. She describes the pain as “tearing from my chest to my back.” Her vital signs are blood pressure (BP), 210/112 mm Hg; heart rate (HR), 142 bpm; respiratory rate (RR) 22 rpm; and temperature, 38.0°C. A BP measurement taken in the other arm is 147/86 mm Hg. An electrocardiogram (ECG) is normal. You are highly suspicious that the patient is suffering from an aortic dissection and order a transesophageal ultrasound examination while contacting the cardiothoracic surgeon. In the meantime, what should you use to lower her blood pressure?
A. Labetalol
B. Nitroglycerine
C. Nitroprusside
D. Phentolamine
E. Treatment should be withheld until a definitive diagnosis is made.

Answer: D. Phentolamine is a direct alpha-adrenergic antagonist and is the drug of choice for sympathomimetic-induced hypertension with end-organ damage. Labetalol and beta-blockers are not recommended, because they have little to no clinical benefit in this setting. Nitroprusside and nitroglycerine are acceptable agents if phentolamine is not available. Treatment should not be withheld, because rapid blood pressure control could be lifesaving.

149.5. A 35-year-old man presents with chest pain that started approximately 2 hours ago, soon after he smoked crack cocaine. The pain occurred with exertion and has not resolved. He has no previous medical history. His vital signs are blood pressure (BP), 182/99 mm Hg; heart rate (HR), 122 bpm; respiratory rate (RR) 18 rpm; and temperature, 38.2°C. His electrocardiogram (ECG) shows sinus tachycardia with ST depression in the anterior leads. The chest radiograph is normal. Laboratory results are significant for elevations in creatine kinase (CK), CK-MB, and troponin I. What is the likely explanation for his elevated serum cardiac markers?
A. He has a completely occluded coronary artery causing ischemia.
B. He has coronary artery spasm without ischemia.
C. He has coronary stenosis causing ischemia.
D. He has fever and rhabdomyolysis but no cardiac disease.
E. His elevated blood pressure is causing cardiac strain but not ischemia.

Answer: C. Although cocaine can cause coronary spasm with resultant chest pain, patients with positive serum markers are likely to have significant angiographic stenosis. Cocaine users who have complete coronary occlusion typically develop ST elevation just as non–cocaine users do. His elevated blood pressure and fever are certainly increasing the workload on the heart but are not causing his elevated cardiac markers. Cocaine patients may suffer from rhabdomyolysis, and although the resultant renal failure can slow the clearance of the cardiac markers, it does not cause the elevation.

149.6. A 24-year-old man is brought to the emergency department (ED) in police custody after he admitted to swallowing multiple packets of cocaine to smuggle them through an airport. The patient has no complaints. His physical examination is normal. An abdominal radiograph shows multiple slightly radiopaque areas consistent with packets of cocaine. An electrocardiogram (ECG) is normal. What is the most appropriate management of this patient?
A. Endoscopic removal of packets
B. No therapy needed; the patient may be discharged
C. Observation alone to watch for elimination of packets
D. Surgical removal of packets
E. Whole bowel irrigation to remove packets

Answer: E. Whole bowel irrigation with polyethylene glycol facilitates passage of the packets and is safe and effective. Endoscopic removal should be avoided, because there is increased risk of packet rupture. Emergent surgical removal is indicated if there is evidence of packet leak and the patient becomes symptomatic. The patient needs to be observed with cardiac monitoring at a center capable of emergent surgery until all packets have passed.

149.7. Which unique life-threatening electrolyte abnormality is seen with the use of N-methyl-3,4-methylenedioxymethamphetamine (MDMA)?
A. Hyperkalemia
B. Hypernatremia
C. Hypokalemia
D. Hypomagnesemia
E. Hyponatremia

Answer: E. Hyponatremia can occur with MDMA use and can be severe and life-threatening. MDMA alters the release of vasopressin and will induce a clinical syndrome resembling the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). The patients have concentrated urine with high urine sodium content. Seizures can occur and should be treated with hypertonic saline. In the absence of seizures or other life-threatening conditions, general supportive care with water restriction is adequate treatment.
Hallucinogens

Janetta L. Iwanicki

The term hallucinogen is used to describe a variety of xenobiotics causing altered perception. A hallucination is defined as perception of an object or sensation that does not exist in reality. However, most drugs do not produce actual hallucinations. Drugs that are classified as hallucinogens are more likely to cause illusions, or misperceptions of real objects. Some hallucinogens are called psychedelics, a subset that alters cognition and perception. Hallucinogens may work by several different mechanisms, including stimulating the serotonergic 5-HT₂₅ receptor, hyperactivation of the dopamine D₂ receptor, and blockade of the glutamate N-methyl-D-aspartate (NMDA) receptors. This chapter describes serotonergic agents, dissociative agents, and selected plants and fungi. Sympathomimetic agents are discussed in Chapter 149.

SEROTONERGIC AGENTS

Principles of Toxicity

Serotonergic agents are a broad category of compounds that share chemical similarities with serotonin (5-hydroxytryptamine [5-HT]) or enhance serotonergic tone within the body, predominantly by their action at the 5-HT₂₅ serotonin receptor subtype. These agents include various lysergic acid derivatives (lysergamides) and tryptamines (indolealkylamines). Serotonin-like agents produce changes in thought, mood, perception, and consciousness. Orientation to person, place, and time is usually preserved, but severe intoxication may cause delirium, disorientation, and altered levels of consciousness. Patients may present to the emergency department (ED) because of an acute panic reaction, massive ingestion, or accidental exposure (eg, children or adults who have ingested the drug unknowingly). There is no addictive potential. In addition to synthetic LSD, several plants contain lysergic acid amide (LSA) similar in structure and action to LSD. These plants include the Hawaiian baby wood rose (Argyreia nervosa), Hawaiian wood rose (Merremia tuberosa), morning glory (Ipomoea violacea), and olooluqui (Rivea corymbosa). Intoxication may result after ingestion of the seeds or an extract.

Tryptamines

Tryptamines may be synthetic or natural compounds. For centuries, Native Central and South Americans have used tryptamine-containing beverages such as ayahuasca in their religious ceremonies. This beverage is brewed from a combination of plants containing dimethyltryptamine (DMT) and 5-methoxy-N,N-dimethyltryptamine (5-MeO-DMT), as well as harmine alkaloids with monoamine oxidase inhibitor effects that increase the bioavailability of orally ingested DMT. Ayahuasca has gained popularity in Europe and North America.

Psilocybin and psilocin are naturally occurring tryptamines found in some species of Psilocybe (Fig. 150.2), Panaeolus, and Conocybe mushrooms. Psilocybin remains active when the mushrooms are dried or cooked. Street psilocybin sold as pills or capsules is frequently substituted with phencyclidine (PCP) or LSD. Naturally occurring tryptamines are also found in the parotid glands of the Bufo toad species. The venom of the Sonoran Desert or Colorado River toad (Bufo alvarius) contains 5-MeO-DMT. Smoking of the dried venom results in psychoactive effects.

Designer tryptamines such as α-methyltryptamine, diisopropyltryptamine, and diisopropyl-5-methoxytryptamine (foxy, foxy methox) have been synthesized and are orally active. The effects of these synthetic derivatives are similar to those of naturally occurring tryptamines.

Clinical Features

In Western society, psychoactive agents are taken for internal mental exploration or, more commonly, for recreation. Effects include loss of boundaries between the user and environment, the sensation that colors and sounds are distorted and intensified, and the perception that usual objects appear novel, fascinating, or awe-inspiring. Users are usually aware that they are under the influence of the drug. A sense of euphoria is typical, but it may alternate with an intense dysphoric experience that is accompanied by suffering (eg, that of dying or being born).

Acute panic reaction is a common adverse reaction to psychedelics. Paranoid delusions and fear of impending death may be present. Behavior may be agitated or withdrawn. Symptomatic effects include dilated pupils and moderate increases in blood pressure, heart rate and, rarely, temperature. Mydriasis seems to parallel the intensity of the trip. The individual’s altered perceptions may result in lack of awareness of dangers in the environment, resulting in injury. Psychosis after LSD trips has been reported, and schizophrenia (overt or borderline) may worsen. Transient depression sometimes occurs after LSD use. Flashbacks, or posthallucinogen perceptual disorder, are transient episodes of altered consciousness that occur months or years after an LSD trip. Hyperactivity may also be seen, with marked auditory and visual hallucinations. Massive ingestions may result in coma and decreased responsiveness to painful stimuli. Fixed and dilated pupils, diaphoresis, vomiting, hyperthermia, rhabdomyolysis, coagulopathy, and seizures may result.

Euphoria and a distortion of reality usually occur after ingestion of one to five Psilocybe cubensis mushroom caps. In contrast...
to peyote (discussed later), vomiting is unusual. Larger doses (5–20 *Psilocybe cubensis* mushrooms) produce visual hallucinations. Few adverse reactions occur, and the incidence of bad trips or panic reactions is lower than with LSD. Rarely, seizures, coma, and hyperthermia have been reported after psilocybin use.

### Differential Diagnoses
Other drugs and mixed ingestion are a possible source of the patient’s symptoms, especially with coma or marked physiologic changes. Cocaine, PCP, anticholinergic drugs, and amphetamines should be considered because their acute effects may require specific treatment. Acute psychosis may also appear, similar to a psychodelic reaction.

### Diagnostic Testing
Often, patients are in a panic or are brought in by a worried companion, so the drug is usually known. Although mass spectrometry can identify psychedelics in serum, urine, or gastric contents, it is not available in the clinical setting, so diagnosis and treatment are based on clinical grounds. Most patients require no laboratory testing, but a basic metabolic profile and ethanol and serum glucose levels may be helpful in patients with unclear ingestions, co-ingestants, or underlying disorders.

### Management
Reassurance and supportive care are the cornerstones of management. If the patient is a danger to himself, herself, or others, the patient may need to be sedated with benzodiazepines (see below) or restrained temporarily to permit sedation. There is no specific antagonist to the effects of serotonergic agents. Empathetic reassurance in a calm, quiet environment with decreased external stimuli is an effective therapeutic modality. The drug effects last for hours but, when it wears off, the patient feels normal again.

Benzodiazepines are the mainstay of treatment for hallucinogenic drug-induced agitation. Diazepam, lorazepam, and midazolam have all been successfully used in this setting. Diazepam can be administered via the intravenous (IV) route in increments of 5 to 10 mg every 5 minutes in adults until sedation is achieved. Diazepam has a rapid onset of action, is easily titratable, and has active metabolites for a sustained effect. Lorazepam, 1 to 2 mg IV every 5 minutes is also an acceptable option. Additional doses of lorazepam or diazepam can be given, with close monitoring of the patient’s respiratory status. For an adult patient in whom IV access is not possible because of agitation, intramuscular (IM) midazolam, 10 mg, can be administered to facilitate subsequent interventions. Although lorazepam also can be given IM, it may take 15 minutes to reach peak sedation, and repeated doses given at more frequent intervals may accumulate, causing oversedation and respiratory depression. In all patients, titration of the benzodiazepine is important, allowing the emergency clinician to observe the effects of one dose (usually 5 minutes) before an additional dose is given. After sedation is achieved, the patient is closely observed to ensure that the patient’s respiratory status is stable when the peak sedation effect is achieved.

The vast majority of patients with hallucinogen-induced agitation respond clinically to adequate doses of benzodiazepines. Butyrophenone antipsychotic agents, such as haloperidol and droperidol, are rapidly effective and generally safe for drug-induced psychosis or agitation states from other drugs, including cocaine, amphetamines, and phencyclidine (also discussed in Chapters 140 and 149). If needed, we recommend haloperidol, 5 to 10 mg IM or IV, which may be repeated every 20 to 30 minutes, as needed for clinical sedation. This medication lacks the respiratory depression potentially caused by other agents and may be beneficial in some cases when rapid sedation is required.

### Disposition
Patients with anxiety or panic reactions are often easily talked down, with little clinical intervention. Acutely toxic patients who respond to sedation and do not have complications can be discharged after the acute toxicity stage resolves following a 4- to 6-hour observation period. We recommend discharging them accompanied by responsible family or friends, with drug counseling and referral. Patients who persist with confused or paranoid behavior should be observed until their mental status returns to baseline. Patients with altered mental status that does not normalize after 8 to 12 hours of observation in the ED, or who present after a massive ingestion with medical complications, require admission to a monitored setting for serial reassessments.

### DISSOCIATIVE AGENTS

#### Principles of Toxicity
PCP and ketamine are the two main agents included in the class of dissociative agents. Dextromethorphan abuse may also
have a similar presentation, and methoxetamine has recently emerged as a new drug of abuse. They are similar in chemical structure and pharmacologic effects and cause dissociation of the patient from the environment. They have analgesic and amnestic activity but do not typically cause respiratory or cardiovascular depression.

**Phencyclidine**

PCP was initially marketed for use as a general anesthetic; however, severe emergence reactions rapidly led to its recall. In the 1960s, PCP was sold as the PeaCe Pill, which was consumed orally, but the effects were often unpredictable and unpleasant. In the mid-1970s, PCP was the most common cause of recreational drug-related emergencies. Its popularity decreased because of unpredictable effects, long clinical course, dysphoria, and association with violence; however, there has been a recent resurgence in popularity in some regions of the United States. In 1978, PCP was classified as a Schedule I drug.

**Ketamine**

Ketamine is known as vitamin K, special K, kit kat, and cat valium; however, preparations available on the street are often adulterated with various stimulants. The most common use of street ketamine is insufflation, but subcutaneous and IM injection and even rectal infusion are done to achieve a level of intoxication or high, known as the K-hole.

**Methoxetamine**

Methoxetamine is a derivative of ketamine known as special M, MXE, Mecxxy, and ROFLceptor, and has been sold as a legal high and an alternative to ketamine, with reports of a lower risk of the urologic complications seen with chronic ketamine use. Symptoms of intoxication are similar to those seen with ketamine, but may also have an increased risk of acute cerebellar toxicity.

**Dextromethorphan**

Dextromethorphan is not truly a dissociative agent but does share a similarity in structure to PCP and its binding to the PCP site of the NMDA receptor. With the availability of concentrated pill formulations, abusers of dextromethorphan can ingest large doses without having to drink large volumes of the less palatable cough syrup formulation. Particularly popular in the adolescent community, dextromethorphan is known as DXM, robo, skittles, triple C, and red hots.

Despite being simple molecules, PCP, ketamine, and methoxetamine have a complex pharmacology, including the NMDA receptor, dopamine-norepinephrine-serotonin reuptake pump, sigma opioid receptor, and cholinergic receptors. PCP is well absorbed from any oral, nasal, or rectal mucous membrane and can be insufflated or smoked. It can be injected IM subcutaneously, or IV. Ingested PCP is well absorbed, with an onset of action between 15 and 60 minutes. When it is smoked, PCP produces symptoms within 5 minutes, with peak activity in 15 minutes. Intoxication with PCP usually lasts 8 to 16 hours but can be prolonged in chronic users. Although enterohemorrhagic recirculation has been proposed, a more likely cause is gastrointestinal concretion or delayed release from lipid stores.

Ketamine is approximately 10% as potent as PCP. With ketamine, the intensity of intoxication is less pronounced, although in larger doses the effects may parallel those of PCP. Duration of action of ketamine is typically shorter, with symptoms lasting approximately 1 hour after insufflation but up to 4 to 8 hours after an oral dose. Methoxetamine appears to have a slower onset and longer duration of action than ketamine. PCP and ketamine are highly lipid-soluble agents that undergo extensive metabolism in the liver and are eventually excreted in the urine.

Although dextromethorphan is typically classified as an opioid, it has a complex pharmacology. Dextromethorphan is the dextrorotatory isomer of the synthetic opioid levorphanol. At high dosages, dextromethorphan is an agonist at the sigma opiate receptor, and nalozone has been reported to reverse intoxication. Dextromethorphan antagonizes the NMDA receptor, which results in its dissociative effects. It also inhibits the uptake of serotonin, and drug interactions with selective serotonin reuptake inhibitors and monoamine oxidase inhibitors have been reported.

**Clinical Features**

Patients with PCP intoxication have a wide spectrum of findings, including sympathomimetic signs and symptoms. Behavior may be bizarre, lethargic, agitated, confused, or violent. A blank or catatonic stare is common. Pupils usually are midsized and reactive, although there may be miosis or mydriasis. Vertical and horizontal nystagmus are often present and considered a hallmark sign of PCP intoxication. Less commonly, rotary nystagmus may be noted with PCP toxicity and should be differentiated from that induced by head injury or brain lesions. Moderate hypertension and tachycardia may be present. Bizarre posturing, grimacing, and writhing may be seen.

Other variable findings include ataxia, muscle rigidity, increased deep tendon reflexes, increased secretions, bronchospasm, hyperthermia, and seizures. Up to 40% of PCP patients may be violent and combative, and control of these patients may be the most challenging problem in the ED. Superhuman strength is possible because of the dissociative and analgesic action of PCP. Rarely, severe hypertension with PCP overdose has caused intracerebral hemorrhage.

Hyperthermia can range from mild to life-threatening. High-output congestive heart failure has been reported. Acute rhabdomyolysis and acute myoglobinuric renal failure are also seen due to muscle damage from seizures, extreme muscle activity such as struggling against restraints, or prolonged immobility. Respiratory depression, apnea, and cardiac arrest have also been described.

Although dextromethorphan has activity at opioid receptors, the typical triad of opioid intoxication—miosis, respiratory depression, and mental status depression—is not generally encountered. Similar to meperidine, dextromethorphan may result in mydriasis through paralysis of the ciliary body with intoxication. Typical clinical findings include lethargy, agitation, slurred speech, ataxia, diaphoresis, hypertension, nystagmus, nausea, vomiting, and hallucinations.

**Differential Diagnoses**

PCP, ketamine, methoxetamine, and dextromethorphan intoxication can mimic such diverse entities as head trauma, meningitis, catatonia, and heat stroke. Sympathetically mediated vital sign changes can be found with numerous other agents, including cocaine, amphetamine, and LSD. Antimuscarinic compounds, such as diphenhydramine, benztprine, and tricyclic antidepressants, can also simulate the tachycardia and altered mental status found with PCP or ketamine. Salicylate poisoning, thyrotoxicosis, and sepsis should be considered. Meningitis, intracerebral hemorrhage, and viral encephalitis can be manifested, with altered mental status of unclear cause. Even with a urine screen positive for PCP, the diagnosis is not certain unless a definite history of recent PCP, ketamine, methoxetamine, or dextromethorphan use is obtained and other conditions have been eliminated.
Diagnostic Testing

Most hospital laboratories use radioimmunoassays that can detect urinary PCP with a detection limit of 5 ng/mL. Urine may be positive for PCP for 2 to 4 days after use and can be positive for more than 1 week. Serum screening for PCP is of little clinical benefit because levels correlate poorly with symptoms. Several substances, including dextromethorphan, may cross-react with urine screens for PCP because of their structural similarities. Chlorpromazine, methadone, mesoridazine, ketamine, diphenhydramine, venlafaxine, meperidine, and tramadol may also cross-react with some assays. In some geographic regions, false-positive test results may be more common than true-positive test results. Because dextromethorphan is typically formulated as a hydrobromide salt, chronic use may result in spurious hyperchlorremia with a low or negative anion gap due to interference of chloride analysis by the bromide ion in the laboratory autoanalyzer. Many dextromethorphan cough and cold preparations also contain acetaminophen; a serum acetaminophen level should be measured. If patients have not been hyperthermic and have no signs of trauma, laboratory or other diagnostic tests are generally not needed. With acutely symptomatic patients, a complete metabolic profile, renal function, and creatine phosphokinase (CPK), serum glucose, and ethanol levels should be measured.

Management

Life-threatening complications, such as apnea and seizures, should be stabilized before transport. The threat of violence to prehospital care providers from patients with PCP intoxication makes it dangerous for only two or three providers to restrain these patients until additional help arrives. Oxygen and glucose testing should be deferred until the patient is controlled. Patients with PCP toxicity can have unpredictable violent behavior, and may sustain traumatic injuries. Extreme agitation, although possible, is less common with ketamine and methoxetamine. Most patients with minor intoxication are alert, oriented, and neurologically normal after 4 to 6 hours. Patients with signs of trauma should be evaluated for injuries. Reliable assessments of these individuals are difficult, and sedation and restraint are often necessary before diagnostic tests or examinations can be performed.

Chemical sedation is preferred to physical restraint with PCP or ketamine intoxication, although temporary physical restraint may be necessary to ensure the patient’s safety, establish IV access, and administer sedating medications. Butyrophenones such as haloperidol and droperidol can be given IM with a rapid response, avoiding the danger of IV establishment. Haloperidol, 5 to 10 mg IM or IV, is usually effective but can be titrated at 10- to 15-minute intervals until the patient is calm. The sedative dose for droperidol is 2.5 to 5 mg IM. These agents may antagonize the CNS receptor sites that are responsible for much of the violent behavior in these individuals. Droperidol has a black box warning from the US Food and Drug Administration (FDA) for QT prolongation and potentially torsade de pointes. However, the FDA added a warning that “torsade de pointes and QT prolongation have been observed in patients receiving haloperidol, especially when the drug is administered intravenously or in higher doses than recommended. Haloperidol is not approved for intravenous use.” Most reported cases of butyrophenone-induced dysrhythmias have been in those receiving large doses for prolonged periods, such as hours to days, or in older adults (>60 years). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when sedation is required. Thus, the butyrophenones remain safe and effective agents for the treatment of drug-induced agitation. Benzodiazepines, such as lorazepam, 2 to 4 mg IV or IM, or diazepam, 5 to 10 mg IV, may also be used to treat agitation (see Chapters 140, 149, and 189).

A well-coordinated team may be needed to apply restraints simultaneously to all four extremities and the body. Assessment of mental status may not be as reliable after chemical sedation, but the benefits of protecting the staff and patient far outweigh the disadvantages.

Hyperthermia is common in severe cases of PCP poisoning. All patients with significant symptoms, psychosis, or history of violent behavior should have their core temperature measured. Individuals with hyperthermia should be treated with rapid sedation to decrease neuromuscular hyperactivity and heat production, intubation if needed to allow for sufficient sedation, and active, evaporative cooling measures (see Chapter 133).

Renal status and the creatine kinase level should be monitored to detect rhabdomyolysis and myoglobinuric renal failure. Seizures should be treated with an IV benzodiazepine (see Chapter 92). Dextromethorphan poisoning can be managed with supportive care and measures to prevent injury to the patient. Sedation with a benzodiazepine may be used for agitation. Respiratory depression may respond to IV administration of naloxone; however, the dissociative effects do not typically respond to naloxone. The patient should improve during 4 to 6 hours postingestion.

Disposition

For nonviolent patients with dissociative agent intoxication, a quiet holding room is ideal for 4 to 6 hours of observation. Patients with violent behavior or obtundation often require admission to the hospital, where close observation and treatment of potential life-threatening complications can be accomplished. Many of these patients can be medically cleared the next day.

MARIJUANA AND SYNTHETIC CANNABINOIDS

Principles of Toxicity

Marijuana is the most common federally illegal drug in the United States. It was used medicinally in ancient times for conditions such as colic and asthma and has been federally illegal since 1937. However, as of 2015, four states (Colorado, Washington, Oregon, and Alaska) and the District of Columbia have passed legislation to legalize recreational marijuana, 20 states have legalized medical marijuana, and 4 states have decriminalized marijuana possession.

Cannabis sativa and Cannabis indica plants are some of the earliest plants grown by humans. Bioactive substances derived from these plants are collectively called cannabinoids. The seedless flowering tops of the female plant are referred to as sinsemilla and are the commonly grown form of marijuana in the United States. The resin from the flowers is made into hashish. Marijuana is smoked, vaporized, or eaten blended into foods. Δ⁹-Tetrahydrocannabinol (THC) is the main psychoactive agent of the more than 61 cannabinoid compounds and approximately 300 other substances present in the cannabis plant, and cannabidiol (CBD) is the major nonpsychoactive component. THC has been associated with some of the adverse effects of marijuana use, including increased agitation, anxiety, and potential for psychosis. Neuroimaging studies have shown that co-ingestion with CBD may modulate and decrease some of these effects, leading to concerns that newer, high-potency, THC-predominant strains of cannabis may lead to a higher risk chemical profile of these plants.6,7

Synthetic cannabinoids have also become readily available. These products are often marketed as novelty herbal incense and labeled “not for human consumption.” They typically come in resealable foil packages and contain various plant leaves sprayed with a solvent mixture of one or several synthetic cannabinoid
Cannabinoids act primarily at cannabinoid receptors CB1R, found mostly in the CNS, and CB2R, found primarily on peripheral immune cells. Discovery of these cannabinoid receptors and their roles in the body has led to interest in further exploration of the therapeutic potential of cannabinoids.

**Clinical Features**

Smoking marijuana leads to rapid and predictable signs and symptoms. Ingestion can cause delayed and sometimes unpredictable effects. The most common effects from smoking of marijuana include alteration of mood and usually relaxation and euphoria. The only reliable physiologic effects are a mild increase in heart rate and conjunctival injection. Other acute peripheral changes include urinary retention, decreased testosterone levels, and decreased intraocular pressure. Short-term memory is impaired, and the ability to perform complex tasks may be adversely affected.

Many users report excessive appetite after marijuana use. Peak blood levels occur within 8 minutes of inhalation, with rapid distribution into tissues, especially tissues with a high lipid content. The duration of perceived effects is usually 2 to 4 hours when the drug is smoked.

Oral ingestion of marijuana edibles may be associated with longer duration of effect (≥6–12 hours), and patients with a massive oral marijuana ingestion may develop profound ataxia, vomiting, agitation, anxiety, and CNS depression requiring medical care.

Edible products often carry high concentrations of THC in relatively small portion sizes and, due to a delayed onset of effect up to 4 hours after ingestion, patients may ingest escalating amounts of product while awaiting the onset of psychoactive effects.

Pediatric exposures to marijuana may lead to hypothermia, ataxia, nystagmus, tremor, tachycardia, injected conjunctiva, and labile affect. Oral ingestion of potent marijuana in children can produce rapid onset of drowsiness, hypotonia, and lethargy, which can lead to coma and airway obstruction and respiratory compromise requiring intubation and ventilatory assistance.

Whereas intoxications with marijuana and synthetic cannabinoids may have some similarities, significant differences have been described. First-generation synthetic cannabinoids such as JWH-018, JWH-073, HU-210, and CP-47 were commonly associated with tachycardia, agitation, nausea and vomiting, altered mentation, and hallucinations. Seizures were also noted with this group of cannabinoids. Second-generation synthetic cannabinoids such as ADB-PINACA and AB-FUBINACA have been associated with more profound agitation and aggression, seizures, tachycardia followed by bradycardia and, less commonly, ischemic stroke and cardiac toxicity.

**Differential Diagnoses**

The presentation that most closely resembles that of marijuana and synthetic cannabinoid intoxication is acute psychosis. Some individuals with underlying and preexisting psychiatric disorders may progress to overt psychosis after heavy or first-time marijuana use. Because marijuana is so readily available, it is commonly a co-intoxicant used with ethanol and other psychotropic agents. Pediatric patients with unknown unintentional exposures may appear similar to patients with sepsis, meningitis, or metabolic disorders. Rarely, marijuana can be adulterated with other substances, such as PCP and other illicit drugs used concomitantly.

**Diagnostic Testing**

Marijuana screening is rarely helpful in the ED. Urinary metabolites of THC are detectable within 1 hour after smoking of marijuana, but a positive urine test result does not correlate with acute intoxication. A single marijuana cigarette can be detected for 72...
hours when a cutoff level of 100 ng/mL is used, and positive urine levels may persist for 3 months after chronic marijuana use. Inadvertent or passive exposure to large amounts of second-hand marijuana smoke in enclosed areas may produce positive urine test results, depending on cutoff levels used. False-positive urine screen results may be produced by efavirenz, ibuprofen, and naproxen. An exception to this is the utility of a urine drug screen for marijuana in pediatric patients with an unclear cause of altered mental status.

Of the synthetic cannabinoids, only HU-210 is expected to trigger a positive THC immunoassay screen as a result of structural homology. Many other synthetic cannabinoids are structurally distinct from THC and do not result in positive THC immunoassay screens.

**Management and Disposition**

Care of patients intoxicated from marijuana and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral administration of benzodiazepines or antipsychotics. Antiemetics (eg, ondansetron 4–8 mg IV, or metoclopramide, 10–20 mg IV) may be used to treat nausea and vomiting induced by the cannabinoid hyperemesis syndrome (CHS) associated with the synthetic cannabinoids and heavy, daily marijuana use. Hot showers are often recommended for patients suffering these symptoms. The precise mechanism whereby hot bathing produces a rapid reduction in the symptoms of CHS is unknown. It has been postulated that hot water may act by correcting the cannabis-induced disequilibrium of the thermoregulatory system of the hypothalamus.

Children who are significantly symptomatic may require admission for a 24-hour observation period.

**Other Agents**

**Mescaline**

Mescaline is a naturally occurring phenylethylamine usually consumed in the form of peyote buttons, which are derived from the small, blue-green cacti *Lophophora williamsii* and *Lophophora diffusa* (Fig. 150.4). They grow in the deserts of the southwestern United States and Mexico.

Peyote has been used in religious ceremonies for 8000 years. Peyote is also contained in the San Pedro cactus (*Trichocereus pachanoi*) of South America and is used ritualistically by Andean Native Americans. These cacti contain many other alkaloids, some of which are also psychoactive. The use of peyote is legal for members of the Native American Church in some states. Adverse reactions (eg, panic attacks) to peyote are rare in structured religious use. Mescaline has an onset of action of 45 to 60 minutes, with a duration of effect lasting 4 to 8 hours. The CNS and physiologic effects of mescaline use are similar to those of LSD, but more vivid hallucinations can occur. Nausea and vomiting are pronounced and almost always precede the hallucinogenic effects, which is an important aspect of the cleansing spiritual ritual.

**Nutmeg**

Nutmeg is a spice derived from the seed of the nutmeg tree, *Myristica fragrans*. Use of nutmeg as a natural and legal psychotropic agent was popularized in the 1960s. Despite lack of any in vivo human studies, myristicin and elemicin have been suggested as the agents responsible for intoxication because their chemical structure resembles that of mescaline. Reports of intoxication are uncommon. Ingestion of 3 to 30 g (1–4 tablespoons) of the spice is said to induce euphoria and hallucinations but is more likely to cause gastroenteritis.

**Salvia**

*Salvia divinorum*, a perennial herb cultivated outdoors in mild climates, is a member of the mint (Lamiaceae) family. Common names for *S. divinorum* are diviner’s sage, mystic sage, magic mint, sage of the seers, Sally-D, ska, and Maria Pastora. Although the plant has been used for divination and shamanism by the Maztec Indians of Oaxaca, Mexico, *S. divinorum* has become popular in the past 20 years for recreational purposes because of its recognized hallucinogenic properties. In 2004, the DEA listed *S. divinorum* as a “drug of concern” but, to date, *S. divinorum* and salvinorin A are not currently controlled under the CSA in the United States.

Several states, however, have instituted or are considering legislation making possession, cultivation, and use of *S. divinorum* or its extracts illegal.

The active ingredient in *S. divinorum* is salvinorin A, a neolaudane diterpene with selective agonist activity for kappa opioid receptors. Salvinorin A appears to have no activity at delta or mu opioid receptors. The threshold dose of salvinorin A to produce hallucinations is comparable to that of synthetic LSD. However, salvinorin A is distinct from more traditional hallucinogens because it does not bind to the 5-HT₂₅ serotonin receptors, as is the case with LSD.

Salvia is usually chewed and spit out or swallowed, and it seems to be absorbed more readily from the oral mucosa than from the rest of the gastrointestinal tract. Effects produced as a result of oral mucosal absorption may persist for 1 hour. Dried leaves can also be smoked. Inhalation of smoke can produce symptoms within 1 minute that subside during 20 to 30 minutes. Sensations experienced are variable but include distortions of color and vision, uncontrollable laughter, and synesthesias, which are confusions of the senses, such as seeing sounds or smelling colors. Salvinorin A is not detected by typical drug screening tests and is not known to cause interference with routine drug screens used in the clinical setting. Management of intoxication from *S. divinorum* is mainly supportive, with emphasis on injury prevention. Use of naloxone, a nonspecific opioid receptor antagonist, may theoretically be helpful for the reversal of psychotropic manifestations.

**Kratom**

*Mitragyna speciosa*, or kratom, is a tree found in tropical and subtropical regions of Asia and Africa. The popularity of kratom
has grown because of reports of its successful use to attenuate symptoms of opioid withdrawal. Because kratom remains easily obtainable from Internet sources, individuals are able to self-administer the perceived remedy, obviating the need for physician supervision. The safety of such a practice is unknown.

Although kratom extract contains more than 25 alkaloids, mitragynine is the most abundantly found in the plant. Mitragynine is an indole alkaloid with structural analogy similar to that of yohimbine and has agonist activity at mu and delta opioid receptors, producing euphoric, analgesic, and respiratory depressant effects. The respiratory depressant effects are more likely to occur when combined with opioids or other respiratory depressants. Despite its structural similarity to yohimbine, a selective antagonist of presynaptic α2-adrenergic receptors, animal studies have suggested that mitragynine is also an agonist at postsynaptic α2-adrenergic receptors and blocks 5-HT2A receptors.

Typically, kratom leaves are chewed, smoked, or brewed into a tea. The leaves may also be ingested in powder or capsule form. Psychotomimetic effects occur within 5 to 10 minutes of use and may persist for 1 hour, with stimulatory effects at lower doses and opioid effects at higher doses. Opioid properties include analgesic, antitussive, antidiarrheal, and emetogenic effects. Reports in the medical literature include intrahepatic cholestasis after abuse for 2 weeks.23

Currently, there are no clinical diagnostic tests available to detect the presence of kratom alkaloids. Treatment of intoxication is supportive. Although coma and opioid activity have been demonstrated with kratom,24 the effectiveness of opioid antagonists in reversing its effects is inconsistent. A withdrawal syndrome characterized by anxiety, restlessness, and nausea treated with an opioid agonist and lofexidine (an α2-agonist related to clonidine) has also been reported.25

**Ibogaine**

Ibogaine is a naturally occurring indole alkaloid found in the roots of the African rain forest shrub *Tabernanthe iboga*. For many centuries, iboga has been ingested by the indigenous peoples of western Africa as a remedy for fatigue, hunger, and thirst and as a sacrament in religious ceremonies. As with many plant-derived agents, ibogaine’s physiologic effects are highly complex and may involve opioid, dopaminergic, serotonergic, glutaminergic, γ-aminobutyric acid (GABA)–ergic, glutamatergic, adrenergic, and cellular ion channel signaling systems.

Although ibogaine is classified as a Schedule I drug, it is still sought after as a treatment to ease opioid withdrawal and diminish craving of other abused drugs. The intensity of visual hallucinations from ingestion of iboga, in contrast to other hallucinogens, are described to be more pronounced with closed eyes. Since the first report in 1990, there have been multiple reported fatalities due to sudden cardiac death within 72 hours of ibogaine use. The mechanism appears to be blockage of the hERG/IKr channel, leading to marked QT prolongation and tachyarrhythmias.26 There are no specific detection tests for ibogaine, and diagnosis is dependent on a history of exposure because clinical findings are largely nonspecific. Management is predominantly supportive, although patients with markedly prolonged QT intervals and evidence of risk for torsades des pointes may require admission to a monitored setting, treatment with IV magnesium supplementation (magnesium sulfate, 2–4 g IV), electrolyte repletion, and possibly overdrive pacing in rare cases.

**Iboxazole Mushrooms**

Iboxazole-containing mushrooms include *Amanita muscaria*, *Amanita pantherina*, *Amanita gemmata*, and *Amanita cothurnata*. *A. muscaria* has a red or yellow cap, with white warty structures on its surface, and grows in forests of aspen, birch, fir, or pine trees (Fig. 150.5). It has been used in Siberia for centuries and is often described in folklore and fairy tales (also see Chapter 158).

The active ingredients are the isoxazole derivatives ibotenic acid and its decarboxylation product, muscimol, which are structural analogues of the endogenous neurotransmitters glutamic acid (excitatory) and GABA (inhibitory) and are thought to act at these respective receptor sites. The excitatory effects characterized by elation, giddiness, hyperactivity, muscle tremors, and distortion of space and time begin approximately 30 minutes to 2 hours after ingestion and are likely to be mediated by ibotenic acid. Following is a phase of tiredness and deep sleep, in which it may be difficult to arouse the patient. During this phase, vivid hallucinations and manic excitement may oscillate with periods of deep sleep. The duration of effect is up to 12 hours. Management of the excitatory phase is similar to that of other hallucinogens previously described in this chapter. Prolonged sleep with *A. muscaria* ingestion requires only observation and supportive care. Tonic-clonic seizures are reported, but occurrences are rare.

Because elements of isoxazole poisoning resemble manifestations of anticholinergic toxicity, these mushrooms have also been referred to as anticholinergic mushrooms; however, belladonna alkaloids are not present. Paradoxically, there has been a high incidence of mistreatment of *A. muscaria* ingestion with atropine because the name implies that it contains muscarine, a cholinergic toxin. However, the amount of muscarine is miniscule. Many texts recommend the use of atropine, but atropine may exacerbate the anticholinergic effects associated with isoxazole mushrooms. It is important to differentiate isoxazole-containing *Amanita* mushrooms from the deadly hepatotoxic cyclopeptide-containing *Amanita* mushrooms, of which *Amanita phalloides* is a member.
KEY CONCEPTS

- Hallucinogens include many types of drugs and chemicals with different associated effects, including action at serotonin receptors, dopamine receptors, and NMDA receptors.
- Diagnosis and management are based primarily on the history and physical examination, with hallmarks of therapy including supportive care, a calm quiet environment, and sedation with benzodiazepines such as diazepam or lorazepam. Severely agitated patients may benefit from butyrophenone antipsychotic agents such as haloperidol and droperidol.
- Screening tests for drugs of abuse are of limited value in the acute management of intoxicated patients.
- Novel synthetic hallucinogens continue to emerge and may have effects from hallucinogenic, serotonergic, and dissociative toxidromes. These drugs are rarely detected by screening tests, and cases of toxicity may occur in regional outbreaks.
- Patients with PCP toxicity can have unpredictable, violent behavior, and may sustain traumatic injuries. Extreme agitation, although possible, is less common with ketamine and methoxetamine.
- Extremely agitated, violent PCP-intoxicated patients may require rapid sedation to decrease danger to the patient and providers. For hyperthermic patients, sufficient sedation to decrease neuromuscular hyperactivity may require intubation, paralytics, and active external cooling to decrease the risk of multiorgan failure and mortality.
- The care of patients intoxicated from marijuana and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral administration of benzodiazepines or antipsychotics. High doses of antiemetics may be necessary to treat the nausea and vomiting associated with synthetic cannabinoids and heavy daily marijuana use—cannabinoid hyperemesis syndrome.
- The central nervous system and physiologic effects of mescaline use are similar to those of lysergic acid diethylamide (LSD) derivatives, but more vivid hallucinations can occur. Nausea and vomiting are pronounced and almost always precede the hallucinogenic effects.

CHAPTER 150: QUESTIONS & ANSWERS

150.1. Intoxication with morning glory seeds will mimic intoxication with which of the following hallucinogens?
A. Ecstasy
B. Ketamine
C. LSD
D. Marijuana
E. PCP

Answer: C. Several plants contain alkaloids similar to LSD, including morning glory and Hawaiian baby wood rose.

150.2. A 14-year-old boy presents with altered mental status. On examination he has mydriasis, nystagmus, and lethargy. There is a history of exposure to skittles. His urine drug screen for drugs of abuse is presumptively positive for PCP. Which toxicant did he ingest?
A. Dextromethorphan
B. Ecstasy
C. Ketamine
D. Psilocybin
E. Synthetic cannabinoids

Answer: A. Dextromethorphan presents with more of a dissociative clinical pattern than opioids. Skittles, red hots, and triple C are street names for over-the-counter tablets of dextromethorphan. Most immunoassays for PCP cross-react with dextromethorphan to give a false-positive PCP report. Ketamine can also give a similar clinical picture, so the history is also necessary to determine which is the most likely intoxicant in the differential.

150.3. Which of the following urine immunoassays is most likely to give a true-positive result for its class of compounds?
A. Amphetamines
B. Benzodiazepines
C. Benzoylecgonine (cocaïne metabolite)
D. Phencyclidine
E. Tetrahydrocannabinol (THC)

Answer: C. The immunoassay screen for cocaine detects its metabolite, benzoylecgonine. Unlike immunoassays for amphetamines, benzodiazepines, phencyclidine, and THC, which may be highly unreliable, inconsistent, or nonspecific, the immunoassay for benzoylecgonine does not typically result in false-positives or false-negatives. Detection of benzoylecgonine is a specific indication of cocaine use in the past 3 days.

150.4. Which of the following mushroom species has hepatotoxic but not hallucinogenic properties?
A. Amanita muscaria
B. Amanita pantherina
C. Amanita phalloides
D. Conocybe smithii
E. Psilocybe cubensis

Answer: C. A. phalloides mushrooms do not have hallucinogenic properties. Their toxicity is mainly hepatic due to a number of cyclopeptide toxins contained in all parts of the mushroom. C. smithii and P. cubensis contain psilocybin and psilocin tryptamines. A. muscaria and A. pantherina contain the isoazolol compounds ibotenic acid and muscimol, which are analogues of glutamic acid (excitatory) and γ-aminobutyric acid (GABA; inhibitory) neurotransmitters, respectively.

REFERENCES
Iron poisoning used to be the leading cause of poisoning death in children. However, in 1997 the U.S. Food and Drug Administration (FDA) required warning labels and implemented changes in the packaging of iron supplements after which there was an abrupt decrease in the number of poisonings and deaths. Although the FDA rescinded its strict packaging restrictions on iron supplements in 2003, iron poisoning currently remains relatively uncommon. In 2013, there were 5249 calls to poison centers concerning iron exposures, yet there were no deaths. Iron (periodic element 26) is an important metal that is essential to the function of hemoglobin, myoglobin, and many cytochromes and enzymes. Certain disease states result from too much or too little iron, such as hemochromatosis and anemia. Iron is absorbed mostly in the small intestine; depending on total body stores, as little as 10% or as much as 95% of the ingested iron is taken into the cell. In the cell, iron has three fates: storage bound to ferritin, transfer to the serum where it is bound to transferrin, or loss when the intestinal cell is sloughed off. Under normal conditions only 15% to 35% of the iron-binding capacity of transferrin is used. Normal serum iron concentrations range from 50 to 150 µg/dL. The total iron-binding capacity (TIBC), a crude measure of the ability of serum proteins (including transferrin) to bind iron, ranges from 300 to 400 µg/dL. When iron concentrations rise after a significant overdose, transferrin becomes saturated so that excess iron circulates free and unbound in the serum. Unbound iron is directly toxic to target organs. Iron has two distinct toxic effects: (1) direct caustic injury to the gastrointestinal mucosa, and (2) impaired cellular metabolism, primarily of the heart, liver, and central nervous system (CNS). The caustic effects of iron on the gut cause the initial symptoms of vomiting, diarrhea, and abdominal pain. Hemorrhagic necrosis of gastric or intestinal mucosa can lead to bleeding, perforation, and peritonitis. Unbound iron moves into cells and localizes near the mitochondrial cristae, resulting in uncoupling of oxidative phosphorylation and impairment of adenosine triphosphate synthesis. Cell membranes are injured by free radical–mediated lipid peroxidation. Furthermore, iron increases capillary permeability and leads to both arteriolar dilation and venodilation, resulting in hypotension. Direct myocardial toxicity decreases cardiac output. Hydration of the iron molecule creates an excess of unbuffered protons, worsening metabolic acidosis. These effects, combined with severe gastrointestinal fluid losses, can lead to shock, cardiovascular collapse, and death.

In an iron overdose, determining the amount of elemental iron ingested is most important, because cellular toxicity depends on the effects of elemental iron. Different formulations of iron salts contain different percentages of elemental iron (Table 151.1). The total amount of elemental iron ingested can be approximated by multiplying the estimated number of tablets by the fraction of elemental iron contained in the tablet. Ingestions of less than 20 mg/kg of elemental iron usually cause no symptoms. Ingestion of 20 to 60 mg/kg results in mild to moderate symptoms, and ingestion of more than 60 mg/kg may lead to severe morbidity and mortality. Although the dose of elemental iron associated with 50% mortality (LD50) is 200 to 250 mg/kg, doses as small as 130 mg of elemental iron have been lethal in children. Newer forms of iron are carbonyl iron and iron polysaccharide: both are non-ionic and associated with lower toxicity. Neither form is directly corrosive; and the conversion to the iron ion, which is responsible for toxicity, is very slow. There are no reported cases of serious toxicity or death from the ingestion of these compounds.

The clinical effects of acute iron poisoning have traditionally been divided into five stages (Table 151.2), but not every patient experiences the effects of every stage in the same time frame. The severity of phase IV features is primarily dose-related, and it is usually during this phase that fatality occurs.

Many toxins are irritating to the gastrointestinal tract and can cause nausea, vomiting, and diarrhea. Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicions for caustic ingestions, certain alcohols, colchicine, and other heavy metals, such as arsenic, inorganic mercury, and iron.

The presence of gastrointestinal symptoms suggests a potentially serious ingestion, whereas absence of gastrointestinal symptoms is usually reassuring. A serum iron concentration measured at 3 to 5 hours after ingestion is the most useful laboratory test to evaluate the potential severity of an iron overdose. Sustained-release or enteric-coated preparations may have erratic absorption, so the serum concentration should be repeated at 6 to 8 hours after ingestion. Peak serum iron below 350 µg/dL is generally associated with minimal toxicity; 350 to 500 µg/dL, with moderate toxicity; and above 500 µg/dL, with severe toxicity. Because iron is rapidly cleared from the serum and deposited in the liver, the concentration of iron after a substantial ingestion may be deceptively low if it is measured many hours after its peak absorption. TIBC is an inaccurate test and is not useful to gauge the severity of iron poisoning.

A screening abdominal radiograph may also be helpful to confirm a recent large ingestion, and should be interpreted in the context of serum levels, as described later. Most tablets that contain a significant amount of elemental iron are radiopaque (Fig. 151.1), although false-negative radiographs may occur with chewable, liquid, and completely dissolved iron compounds. Repeated radiographs can also demonstrate the efficacy of gastrointestinal decontamination efforts.
MANAGEMENT

Decontamination

Activated charcoal does not bind iron. Both gastric lavage and ipecac are ineffective and not recommended. Symptomatic patients with iron toxicity generally present with vomiting early in the clinical course. Iron tablets clump together as their outer coatings dissolve, often forming large pharmacobezoars. Whole bowel irrigation (WBI) is generally the preferred method of decontamination for significant iron ingestions. Early, rapid decontamination of the gastrointestinal system may obviate the need for or shorten antidotal therapy.

For significant ingestions, especially when the number of tablets identified by abdominal radiography indicates a likely toxic dose, WBI with a polyethylene glycol–electrolyte solution (PEG-ELS) should be initiated. The solution should be administered through a small nasogastric tube. The recommended rate of administration of PEG-ELS is 500 mL/hr in children 9 months to 6 years old, 1000 mL/hr in children 6 to 12 years old, and 1.5 to 2 L/hr in adolescents and adults. WBI is continued until the rectal effluent is clear and there is no radiographic evidence of pill fragments. This technique has been used in children, adolescents, and pregnant women without serious complications or electrolyte disturbances. Common side effects include nausea, vomiting, abdominal cramping, and bloating. WBI is contraindicated in the presence of bowel obstruction, perforation, ileus, or hemodynamic instability.

*Typical duration of symptoms, post-ingestion is also given.
Enhanced Elimination

Hemodialysis and hemoperfusion are not effective in the removal of iron because of its large volume of distribution. On the other hand, early exchange transfusions have been used with some success for severely symptomatic patients. However, this should only be considered in patients who are not responding to standard therapy.

Antidotal Therapy

Deferoxamine is the specific antidote for iron toxicity. Deferoxamine chelates iron to form the water-soluble compound ferrioxamine, which is renally excreted. Deferoxamine binds to free iron and will not chelate iron from hemoglobin, transferrin, or ferritin. Patients with an iron concentration above 500 µg/dL and those who, regardless of level, are exhibiting severe signs and symptoms of iron toxicity (such as, metabolic acidosis, repetitive vomiting, toxic appearance, lethargy, hypotension, or signs of shock) require chelation. Pregnancy is not a contraindication to deferoxamine. However, the pre-pregnancy weight should be used to calculate the ingested dose. Because of its short half-life, deferoxamine is administered as a continuous intravenous infusion at 15 mg/kg/hr for up to 24 hours. The maximum rate of administration is 35 mg/kg/hr. More rapid administration of deferoxamine can lead to hypotension, which is managed by reducing the initial rate of the infusion and then slowly increasing it to the desired rate. Deferoxamine has been associated with acute respiratory distress syndrome and also with *Vesnella* sepsis. The pulmonary complications are usually related to high-dose deferoxamine for durations longer than 24 hours.

**DISPOSITION**

The asymptomatic patient who is reliably known to have ingested less than 40 mg/kg of elemental iron does not need additional therapy and can be discharged home after appropriate poison prevention counseling. In patients who ingest more than 40 mg/kg, an iron concentration should be obtained at 3 to 5 hours post-ingestion and also 6 to 8 hours post-ingestion. If peak iron remains less than 300 µg/dL, is not rising, and the patient is asymptomatic during 6 hours of observation, the patient can be discharged home. If the patient is exhibiting signs of severe toxicity, even if the ingested dose is unknown, or meets criteria for deferoxamine, admission to an intensive care unit and poison center or toxicologist consultation is advised. If indicated, a psychiatric consultation should be requested.

**LEAD**

**PRINCIPLES OF TOXICITY**

Lead poisoning remains one of the most common and preventable environmentally mediated problems in the United States. The elimination of leaded gasoline and the ban on leaded paint in households in the 1970s exponentially reduced the number of lead poisonings in the United States. However, the Center for Disease Control and Prevention (CDC) estimates that approximately 535,000 children, aged 1 to 5 years old, still have elevated blood lead levels (BLLs) from various environmental exposures. Immigrant and refugee children are at much greater risk for lead poisoning than children born in the United States because of diet and other exposure risks prior to arrival in the United States. The CDC also estimates 1.2 million adult workers have BLLs above 25 µg/dL based on a workplace surveillance program. Given the continued wide use of lead in industry, there are many potential sources of exposure (Table 151.3).

</table>

Most lead exposures occur by ingestion in children and workplace inhalation in adults. Dermal absorption may also occur but is much less significant. Children and pregnant woman absorb almost four times the amount of ingested lead than other adults. Once absorbed, lead is bound to red blood cells and slowly distributes to the soft tissues where it is eventually stored primarily in bone. Lead easily crosses the placenta, and maternal blood levels correlate with cord blood levels. Neonatal lead exposure also occurs through breast milk. The half-life of lead in the red blood cell is about 30 days, but once in the bone the half-life lasts decades. Most lead is excreted in the urine and bile.

There is no biological role for lead in the human body. Lead (periodic element 82) complexes with sulfhydryl groups of proteins, which can alter enzyme and receptor function and distort structural proteins. Lead is also structurally similar to calcium and interferes with calcium dependent cellular processes. Its toxic effects are most prominent in the hematopoietic and neurologic systems.

**CLINICAL FEATURES**

The clinical features of lead poisoning are broad and often nonspecific (Table 151.4). Symptoms depend on the BLL, whether the patient is an adult or child, and whether the exposure is acute or chronic. Although all organ systems are affected, the most sensitive are hematologic, vascular, and nervous systems. Because routine lead screening is done less commonly today, many cases are now identified as a result of an anemia evaluation. Through inhibition of heme biosynthesis, the classic manifestation of hematopoietic lead toxicity is anemia. Anemia may be either normochromic or hypochromic. Chronic kidney disease and hyperuricemic gout (“saturnine gout”) can also result from elevated BLLs. Chronic kidney disease consequently may worsen underlying anemia. Lead poisoning has been shown to be associated with hypertension. In the peripheral nervous system, segmental demyelination and degeneration of motor axons result in peripheral neuropathy. Wrist-drop and foot-drop are characteristic of adult lead poisoning but rarely seen today. Most importantly, lead toxicity causes many different neuropsychiatric disorders. Many are difficult to distinguish during an emergency department (ED) evaluation, so collaboration with a primary physician is
essential to identify new deficits. In children, elevated BLL is associated with decreased intelligence quotient (IQ) scores, hyperactivity, decreased attention span, overaggressive behavior, learning disabilities, and criminal behavior. Severely high BLLs may present with lead encephalopathy associated with increased capillary permeability and cerebral edema.

**DIFFERENTIAL DIAGNOSES**

The differential diagnosis of lead poisoning is broad, and because the symptoms of early poisoning are so nonspecific, lead poisoning today is often initially misdiagnosed. Lead poisoning could be confused for neuropathies (such as, carpal tunnel or Guillain-Barre syndrome) or abdominal pathologies (such as, gastroenteritis, nephrolithiasis, or appendicitis). The subtle neuropsychiatric signs in children can also be misdiagnosed as attention deficit hyperactivity disorder or other behavioral disturbances. Therefore, it is necessary to consider lead poisoning in the appropriate circumstance, particularly where another diagnosis is not established as the cause of the presentation. Perform a careful and detailed neurologic examination, and evaluate patients for potential sources of exposure.

**DIAGNOSTIC TESTING**

Lead toxicity rarely presents primarily to the ED. Most patients encountered in the ED have been referred for management of an elevated screening BLL done in clinic or workplace surveillance program. Some patients may seek ED care following an ingestion of a leaded foreign body or with worrisome symptoms and an exposure history. Diagnostic testing should consist of a venous BLL, including those cases referred in for an abnormal screening test, because those screens may be falsely elevated. If the patient is symptomatic, other tests include a complete blood cell count, basic metabolic panel, liver functions tests, and urinalysis. A peripheral smear classically shows basophilic stippling, but that finding is relatively rare. Because lead-containing objects and paint chips are radiopaque, abdominal radiographs can confirm acute ingestion and determine the need for bowel decontamination. In cases of altered mental status, seizures, or coma, a computed tomography (CT) scan of the head may show cerebral edema associated with acute lead encephalopathy and rule out other causes of these neurologic signs. In children, plain radiographs of the wrist and knees classically demonstrate increased metaphyseal activity termed as “lead lines” that are characteristic of chronic exposures. However, such x-rays do not need to be routinely done in the ED.

**MANAGEMENT**

The most important treatment step in lead poisoning is removing the patient from the source. This is the only treatment needed in most cases of lead poisoning. However, determining the exact source often requires the collaborative assistance of a primary care physician, social workers, and the department of public health. Recent data suggest urban patients at risk for lead poisoning are also at risk for asthma—the environmental evaluation for lead and asthma risks is similar, so ensuring follow-up with a primary care provider to assess the risk for both problems is essential.

**Decontamination**

Activated charcoal does not bind lead. If an abdominal radiograph demonstrates lead within the gastrointestinal tract, particularly the stomach and small intestine, or a leaded foreign body or multiple foreign bodies are present, then bowel decontamination should be performed. This can be done with WBI or repeated polyethylene glycol administration (see the Iron section for dosing regimen).

**Antidotal Therapy**

**Children**

Treatment for lead toxicity rarely is commenced in the ED. Information on chelation therapy is provided here for reference. Evidence indicates no benefit from chelation for children with a BLL lower than 45 µg/dL. A BLL between 20 and 44 µg/dL in a patient who is asymptomatic or minimally symptomatic requires a medical and environmental evaluation to identify the source and stop further exposure. Children with lead levels of 5 to 19 µg/dL require caregiver education about worrisome symptoms and sources of lead exposure with close follow-up with a primary caregiver. An environmental evaluation can often be arranged with the local public health department.

Blood lead levels of 45 to 69 µg/dL in patients without vomiting or CNS symptoms can be managed in the outpatient setting with oral succimer (2,3-dimercaptosuccinic acid [DMSA]; Chenet). The initial dose of succimer is 10 mg/kg every 8 hours for 5 days, then 10 mg/kg every 12 hours for 14 days. The most common adverse reactions include nausea, vomiting, diarrhea, and transient elevations in liver transaminase levels. Although succimer has been FDA approved only for children, it is effective and also used for adults. Table 151.5 summarizes available chelating agents with indications and doses. Any patient treated on an outpatient basis should be discharged to a lead-free environment.

Patients with a BLL of 69 µg/dL or higher require hospitalization and parenteral chelation therapy, even if asymptomatic or minimally symptomatic. Evidence of encephalopathy also requires admission for parenteral chelation therapy. Consultation with a medical toxicologist, regional poison center, and pediatrician is indicated. Dimercaprol (or British anti-Lewisite [BAL]) should be given first at a dose of 75 mg/m² by deep intramuscular injection.
every 4 hours for 5 days for children or 4 mg/kg every 4 hours for adults. Adverse reactions to BAL include nausea, vomiting, urticaria, pyrexia, hypertension, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Because BAL is diluted in peanut oil, it is contraindicated in patients allergic to peanuts. In cases of encephalopathy, intravenous calcium disodium ethylenediaminetetraacetic acid (CaNa₂EDTA) should be initiated with the second dose of BAL, because starting treatment with CaNa₂EDTA may paradoxically increase lead transport across the blood brain barrier. The dosage of CaNa₂EDTA for patients with acute lead encephalopathy is 1500 mg/m²/day (approximately 50 to 75 mg/kg/day) given by continuous intravenous infusion also for 5 days. Adverse reactions include renal tubular injury and chelation of other metals, especially iron and zinc. CaNa₂EDTA should be given only with adequate urine flow or with hemodialysis in the patient with renal failure. For patients with a BLL more than 69 µg/dL but no signs of encephalopathy, the dosage of CaNa₂EDTA is 50 mg/kg/day or 1000 mg/m²/day, given in two to four divided doses for up to 5 days without the need for concurrent BAL.

Adults

The treatment of adults with chronic poisoning is based primarily on symptoms and threshold treatment BLLs established by workplace regulatory agencies. In the asymptomatic adult or the adult with only mild clinical problems, the only intervention needed is cessation of exposure. According to the Occupational Safety and Health Administration (OSHA) lead standard, workers with serum lead levels above 40 µg/dL should be removed from work. If encephalopathy or severe symptoms are present, then hospitalization and chelation therapy with combined BAL and CaNa₂EDTA, as in children, are indicated. Pregnant women should be treated in accordance with adult treatment guidelines. Lead does cross the placenta and can accumulate in the fetus. The newborn may require chelation as well.

**DISPOSITION**

Families of asymptomatic children with BLLs less than 45 µg/dL and asymptomatic adults should be counseled on how to avoid further exposure and given close follow-up with their primary care provider for a repeat BLL and further exposure risk evaluation.

Patients who require oral chelation can be discharged home if they can tolerate succimer and if it can be ensured they do not return to a lead-contaminated environment. The health department should conduct an environmental assessment and other family member testing so that the primary source of lead exposure can be identified and further exposure prevented. Follow-up should be arranged with an experienced pediatrician, toxicologist, or occupational medicine physician.

Patients who are significantly symptomatic, have worrisome CNS symptoms, and any children with a BLL of 69 µg/dL or higher require hospitalization for environmental exposure evaluation and chelation therapy.

**ARSENIC**

**PRINCIPLES OF TOXICITY**

Arsenic (periodic element 33) has an infamous history as an agent of homicide and has been implicated in mass environmental poisonings. Currently, arsenic exposure is primarily environmental and occupational. Arsenic is found in smelters and electric power plants that burn arsenic-rich coal; in the production of glass and microcircuits; and in rodenticides, fungicides, insecticides, paint, tanning agents, defoliants in the cotton industry, and in wood preservatives. Arsenic is also still used for medicinal purposes in the treatment of trypanosomiasis, amebiasis, and leukemia. Importantly, significant concentrations of arsenic have been found as a contaminant in ayurvedic medications. Arsenic has also been reported in low-income countries with large environmental poisonings via well water.

Arsenic exists in different forms: elemental, organic, inorganic, and gaseous. Elemental arsenic (As) is a metal that is poorly water soluble and is considered nontoxic. Organic arsenic, found in shellfish, is also generally non-toxic. Of the two inorganic forms, trivalent arsenite (As$^{3+}$) is more toxic than the pentavalent arsenate (As$^{5+}$) form. Absorbed arsenic is bound by hemoglobin, leukocytes, and plasma proteins. It is cleared from the intravascular compartment within 24 hours and concentrates in the liver, kidneys, spleen, lungs, and gastrointestinal tract. Arsenic crosses the placenta and can also accumulate in the fetus. Inorganic arsenic interferes with normal cellular metabolic function, energy generation, and induces apoptosis. Arsenic also generates reactive oxygen species and induces oxidative damage in the cell. Gaseous arsenic in the form of arsine (AsH$_3$) is colorless, almost odorless, and extremely toxic. It is immediately lethal at 250 ppm. The excretion of arsenic and its metabolites occurs mainly through the kidneys. Arsenic has no metabolic or biologic function.

**CLINICAL FEATURES**

**Acute Arsenic Toxicity**

Gastrointestinal effects including nausea, vomiting, abdominal pain, and diarrhea predominate as the initial manifestations of acute exposure to inorganic arsenic. The diarrhea has often been described as “rice water-like” and difficult to differentiate from diarrhea induced by cholera infection. These symptoms can be so severe as to be manifested with hematemesis and hematochezia. The patient can also have encephalopathy with seizures and coma, respiratory failure associated with acute respiratory distress syndrome, and dysrhythmias associated with cardiac conduction disturbances, such as QT prolongation and torsades de pointes (Box 151.1). In cases of severe poisoning, cardiovascular collapse and death ensue. Early arsenic poisoning syndrome may be misdiagnosed as gastroenteritis or sepsis. For those who survive the initial gastrointestinal illness, chronic effects of arsenic poisoning appear weeks to months later. These include characteristic lines in the nails (Aldrich-Mees lines; Fig. 151.2), painful sensorimotor neuropathy, and hyperkeratosis of the palms and soles.

**BOX 151.1**

**Acute Effects of Arsenic Poisoning**

| GASTROINTESTINAL | Pulmonary edema
| Severe gastroenteritis; hematemesis or hematochezia | Pneumonia
| Jaundice | Renal
| Pancreatitis | Proteinuria
| Dysphagia | Hematuria
| Hepatomegaly | Oliguria
| CARDDIOVASCULAR | Renal failure
| Third spacing with shock | Neurologic
| Sinus or ventricular tachycardia | Headache
| Prolonged QT interval, ST depression, T wave inversion | Drowsiness
| Torsades de pointes | Delirium
| Pericarditis | Coma
| REPRODUCTORY | Encephalopathy
| Respiratory Failure | Seizures
| Acute respiratory distress syndrome |
Chronic Arsenic Toxicity

Chronic exposure to arsenic, typically through contaminated drinking water or occupational exposure, is associated with cardiovascular disease, diabetes mellitus, and dermatological disease both malignant and nonmalignant. Furthermore, patients chronically exposed to arsenic have an increased risk of bladder, kidney, liver, and lung cancer.

Arsine Gas

Acute exposure to arsine gas is characterized by severe hemolysis that is also associated with renal tubular injury. Signs of toxicity are usually evident within minutes to hours after exposure. Gastrointestinal symptoms are common, and CNS and liver dysfunction can occur.

DIFFERENTIAL DIAGNOSES

Acute arsenic poisoning is often misdiagnosed as some form of gastroenteritis or gastrointestinal bleeding. Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicion for caustic ingestion, heavy metals, and iron. Obtaining an environmental and occupational exposure history is important to help discern the etiology of the patient’s symptoms.

DIAGNOSTIC TESTING

To diagnose arsenic poisoning accurately, a 24-hour urine collection should be done. Spot urine samples are inaccurate and do not guide therapy. Normal arsenic concentrations are 5 µg/L or less in blood or less than 50 µg/day in a 24-hour urine collection. Any urine level above 100 µg/day or 50 µg/L necessitates treatment. Seafood contains arsenobetaine, which can significantly increase total urine arsenic concentrations, but arsenobetaine does not result in toxicity. For this reason, patients should refrain from eating seafood, specifically shellfish, before testing, and the laboratory should be asked to speciate the type of arsenic measured. Most patients referred to the ED for management of abnormal urine arsenic tests today are not arsenic toxic; their urine tests are falsely abnormal because laboratories do not routinely differentiate between arsenobetaine and inorganic arsenic. In cases of chronic arsenic poisoning or remote exposure, the serum and urine arsenic levels may no longer detect abnormal concentrations of arsenic.

Other laboratory results may suggest arsenic poisoning. Anemia, leukocytosis or leukopenia, and erythrocyte basophilic stippling may be seen in the complete blood cell count. The results of renal function tests may be abnormal, demonstrating proteinuria, hematuria, and pyuria. The alanine transaminase, aspartate transaminase, and bilirubin levels may be elevated.

Arsenic in the gastrointestinal tract is radiopaque and can appear on a radiograph, although sensitivity is limited by its rapid absorption and the ensuing gastroenteritis.

MANAGEMENT

Initial management of arsenic poisoning should address life-threatening conditions with supportive care of shock, dysrhythmias, and seizures.

Decontamination and Enhanced Elimination

As is the case with other metals, activated charcoal does not adsorb arsenic and is not recommended. Hemodialysis may remove some arsenic in the setting of acute renal failure. Exchange transfusions or plasma exchange can be done early after a severe arsine exposure. These treatments should be initiated in the intensive care setting for critically ill patients and in consultation with a medical toxicologist.

Antidotal Therapy

Acute Arsenic Poisoning

With a confirmed history of exposure in a symptomatic patient, chelation should start as early as possible without waiting for laboratory confirmation. Intramuscular BAL is the preferred chelator in patients who are critically ill as described for lead poisoning. Succimer can be given orally, but its use is often limited by the severe gastroenteritis resulting from arsenic poisoning. n-Penicillamine has a high side effect profile and is much less effective than BAL or succimer, so it should be used only when BAL or succimer are unavailable. Table 151.5 summarizes available chelating agents with indications and doses. Chelation is not useful for arsine gas exposures. With arsine gas poisoning, exchange transfusion, continuous venovenous hemodialysis, and plasma exchange have been used to remove arsine, which is tightly bound to erythrocytes. Fluid resuscitation helps kidney perfusion early after exposure.

Chronic Arsenic Poisoning

Treatment of chronic arsenic toxicity should begin in a symptomatic patient after confirmation of elevated urinary arsenic levels. Oral chelation with succimer is the treatment of choice. Workers should modify their habits to avoid further absorption, and repeated monthly 24-hour urine collections can follow arsenic excretion. Chelation treatment in patients with chronic exposure but no detectable arsenic in blood or urine has not been proven to be effective.

DISPOSITION

All patients who are severely ill and those receiving chelation for acute arsenic toxicity should be admitted. Chronic arsenic exposure in a mildly symptomatic patient can be discharged home after removal from the source of exposure and close follow-up with occupational medicine or a medical toxicologist is ensured. Those who are asymptomatic with normal physical examination and vital signs can be sent home.

MERCURY

PRINCIPLES OF TOXICITY

Mercury (periodic element 80) is a silver-white metal, familiar to most as one of the few metals that is liquid at room temperature in its elemental form. Others include bromine and gallium. It has a long history of medicinal uses as an antiparasitic, a diuretic, a cathartic, an antiseptic, and a preservative in many vaccines.

Significant poisoning can occur in the home and also in the workplace. Mercury has many industrial uses that include the manufacture of fluorescent lights, batteries, polyvinyl chloride, and latex paint. Recently, artisanal small scale gold mining has become a significant source of global mercury pollution and toxicity. For these reasons, mercury is a common pollutant of air and water. This has led to restrictions in the consumption of fish caught in many local waters, especially by pregnant women and children.

Like other metals, mercury exists in different forms and toxicity depends on the form of exposure: elemental, organic, and inorganic. The most familiar form of mercury is elemental or “metallic” mercury, also known as quicksilver. A common route of exposure
to elemental mercury is the inhalation of volatilized vapor during mining or after vacuuming up a spill. After inhalation, metallic mercury is retained in the lung that can result in pneumonitis and acute respiratory distress syndrome; systemic absorption may also occur. Subcutaneous and intravenous injections also cause poisoning from systemic absorption. Aspiration of elemental mercury results in primary pulmonary toxicity in addition to CNS and renal toxicities. Elemental mercury is not well absorbed by the gastrointestinal tract and toxicity is unlikely by this route. Inorganic mercury salts have two different valences: Hg\(^{2+}\) (mercurous) and Hg\(^{4+}\) (mercuric). Ingestion of either salt leads to significant gastrointestinal and renal toxicity. Inorganic salts have a direct corrosive effect on the gastrointestinal tract with third spacing and hemorrhage.

The organic mercury compounds are categorized as either short chain (alkyl) or long chain (aryl). The major route of exposure to this type of mercury is through ingestion, but these compounds are also readily absorbed through the skin. These organic forms classically result in delayed neurotoxicity, and most medical evidence about this form of toxicity comes from large population epidemics. Recent concerns about mercury poisoning from excessive fish consumption are extrapolations from those epidemics.

Mercury has no known physiologic role. Mercury binds covalently to sulphydryl groups, disturbing multiple cellular enzyme functions. Nephrotoxicity results from both direct damage and an immune reaction in the kidney. Mercury exposure affects both the cardiovascular system and the CNS. Mercury may lead to hypertension and other cardiovascular problems. Mercury also inhibits microtubule organization in the nervous system, which is vital to its function. The mechanisms by which these effects occur are still being discovered. Although mercury used to be a preservative in various vaccines, it is important to note the dose in those vaccines is relatively low, and mercury has not been confirmed to be a cause for autistic spectrum disease.

**CLINICAL FEATURES**

The clinical manifestations of mercury poisoning depend on the acuity of the exposure, the route of exposure, and the chemical form of mercury (Table 151.6).

**DIFFERENTIAL DIAGNOSES**

Hemorrhagic gastroenteritis in the setting of an ingestion history should raise suspicions for caustic ingestion, heavy metals, and iron. Respiratory distress from elemental mercury inhalation can also be mistaken for pneumonia, asthma, or influenza. Obtaining an environmental and occupational exposure history is important to help discern the etiology of the patient’s symptoms.

**DIAGNOSTIC TESTING**

Measurement of 24-hour urine mercury concentration is the most helpful test in confirming exposure and monitoring the effectiveness of chelation. For organic mercury compounds, which undergo little urinary excretion, serum concentration should be used to confirm the diagnosis. “Normal” mercury is considered to be less than 10 µg/L in the blood or less than 20 µg/L in the urine. Blood concentration above 35 µg/L and urine above 150 µg/L require intervention. Fish can be contaminated with mercury, especially larger fish and those from certain bodies of water known by local health departments to be most polluted. Individuals eating these locally caught fish will have elevated mercury levels. Elemental (metallic) mercury is radiopaque on plain radiographs, which can be ordered in cases of injection or ingestion of elemental mercury (Figs. 151.3 and 151.4). Subacute or chronic inhalation of metallic mercury Aspiration of metallic mercury Subacute or chronic inhalation of mercury Organic mercury exposure (methyl-, diethyl-) Ingestion of inorganic mercury salts Inhalation of metallic mercury

**TABLE 151.6**

**Mercury Poisoning and Clinical Manifestations Based on Route of Exposure and Form of Mercury**

**MANAGEMENT**

Initial management in the acutely poisoned patient is supportive. Activated charcoal and other gastrointestinal decontamination strategies are not recommended.

For acute inhalational exposures, the patient should be removed from the source and supportive management provided. There is...
DISPOSITION

Ingestion of inorganic mercury in patients with any symptoms warrants admission for further evaluation and supportive treatment. Patients who self-inject metallic mercury may need surgical consult for surgical débridement; this may be done as an outpatient if no symptoms or abnormal signs are evident. Patients with signs of neurotoxicity from organic mercury need admission. Asymptomatic patients with exposure to any form of mercury warrant environmental counseling, and those with concerns from excessive fish consumption need primary care or medical toxicologist follow-up as outpatients for dietary counseling and testing if indicated.

KEY CONCEPTS

- Asymptomatic patients seeking ED care for an abnormal metal test need follow-up evaluation arranged with a medical toxicologist.
- Metal testing in the ED should only be ordered in consultation with a medical toxicologist or regional poison center.
- Acute ingestion of the salts of most metals causes rapid severe gastrointestinal pain and emesis.
- Any abnormal neurologic signs in a patient with any metal exposure warrants admission for further evaluation and chelation therapy.
- Acute iron poisoning can result in gastrointestinal symptoms, metabolic acidosis, and hepatoxicity. Serum iron levels at 3 and 6 hours after ingestion determine toxicity and need for therapy.
- The chelation agent of choice for severe iron poisoning is deferoxamine and is indicated for peak serum iron concentrations greater than 500 µg/dL and patients with severe signs and symptoms regardless of the iron level.
- The most important intervention for lead poisoning is removal from the source of exposure.
- The gastrointestinal decontamination method of choice for iron and lead toxicity with radiographic presence of pills or paint chips is WBI.
- The chelation agent of choice for acute arsenic poisoning is intramuscular British anti-lewisite (BAL) or oral succimer.
- Elemental mercury is nontoxic to the gastrointestinal tract but may cause pulmonary and CNS toxicity from inhalation of volatilized vapors.

CHAPTER 151: QUESTIONS & ANSWERS

151.1. Which of the following laboratory tests is most useful in a suspected iron overdose? 
A. Aspartate aminotransferase  
B. Ferritin  
C. Serum iron  
D. Total iron-binding capacity (TIBC)  
E. Transferrin

**Answer:** C. The serum iron level is most helpful when it is measured at its peak, 3 to 5 hours after ingestion, and is the most useful to predict toxicity. Levels below 350 μg/dL are generally safe, whereas levels above 500 μg/dL indicate the potential for severe toxicity. At levels in between, the severity of the symptoms guides treatment.

151.2. A 20-year-old man presents after an iron overdose. An abdominal radiograph shows many radiopaque objects in his stomach, consistent with iron tablets. You decide to try to decrease the gastrointestinal absorption of the iron. Which of the following methods is most effective? 
A. Activated charcoal  
B. Gastric lavage  
C. Surgical removal  
D. Syrup of ipecac  
E. Whole bowel irrigation (WBI)

**Answer:** E. WBI is the preferred method to minimize iron absorption. WBI should not be routinely used is small overdoses or with mild symptoms, but it should be considered when a significant ingestion is suspected or when multiple tablets are identified by radiography. Iron is not adsorbed to activated charcoal. Gastric lavage and syrup of ipecac do not remove significant amounts of iron. Open surgical removal of tablets has been used in the past and is effective, but it is obviously invasive and has a higher rate of adverse outcomes than WBI.

151.3. A 5-year-old boy presents with abdominal pain, nausea, vomiting, and bloody diarrhea. The boy was found rummaging through his grandmother’s medicine cabinet and may have ingested some of her medications. His vital signs are significant for hypotension and tachycardia. An electrocardiogram (ECG) shows only sinus tachycardia. Laboratory tests are significant for an anion gap acidosisis, hyperglycemia, and moderate leukocytosis. Which of the following medications did he most likely ingest? 
A. Digoxin  
B. Diltiazem  
C. Iron  
D. Metformin  
E. Metoprolol

**Answer:** C. Iron toxicity typically presents with gastrointestinal symptoms including occasional bleeding soon after ingestion. The previously mentioned laboratory findings are also typical.Digoxin toxicity can also be manifested with gastrointestinal symptoms, but there is usually no gastrointestinal bleeding and there are also typically ECG changes. Beta-blocker toxicity, such as with metoprolol, is manifested with hypotension and bradycardia, as well as...
with hypoglycemia. Calcium channel blocker toxicity, such as with diltiazem, can be manifested with gastrointestinal symptoms, acidosis, and hyperglycemia. However, patients typically have bradycardia, and gastrointestinal bleeding is not expected. Metformin toxicity is manifested with gastrointestinal upset, typically without bleeding. Lactic acidosis can result, but the vital sign abnormalities and other laboratory results are not expected.

### 151.4.
A 45-year-old man presents with difficulty walking and fatigue. His vital signs are normal. His physical examination is significant for pale conjunctiva and a foot-drop. Serum electrolyte values are normal. A complete blood count is significant for a hypochromic anemia. Which of the following metals is most consistent with these findings?

A. Arsenic
B. Iron
C. Lead
D. Mercury
E. Tin

**Answer:** C. Lead

### 151.5.
Which of the following laboratory tests would you expect to have an abnormal result in a child with the radiograph shown here.

A. Calcium
B. Iron
C. Lead
D. Mercury
E. Parathyroid hormone

**Answer:** C. This radiograph illustrates “lead lines,” which indicate increased metaphyseal activity. This finding is common in children suffering from chronic lead exposure.

### 151.6.
A 24-year-old man presents after attempting suicide by ingesting approximately 10 g of mercury that he collected from thermometers. The ingestion occurred approximately 30 minutes ago. He has no complaints currently. His vital signs and physical examination findings are normal. An abdominal radiograph reveals a radiopaque mass in his epigastrium. Other than psychiatry consultation, what treatment is indicated?

A. Dimercaprol
B. Hemodialysis
C. No treatment
D. Succimer
E. Whole bowel irrigation (WBI)

**Answer:** C. Ingested metallic mercury is poorly absorbed and poses no health risk as long as it is passed from the body and not trapped in the appendix or a diverticulum. Inorganic mercury salts are quite toxic, and patients exposed to these should be treated with succimer or dimercaprol. Organic mercury is typically not acutely toxic but does cause significant chronic disability and should be treated with succimer because treatment with dimercaprol can actually increase levels of mercury in the central nervous system (CNS). Hemodialysis is not effective.
PRINCIPLES OF TOXICOLOGY

Hydrocarbons are a diverse group of organic compounds that contain hydrogen and carbon (Table 152.1). Most hydrocarbons (eg, gasoline) are byproducts of crude oil and are therefore called petroleum distillates. Essential oils such as turpentine or wormwood are derived from plants and not petroleum. Hydrocarbons are used as solvents and diluents in many products, such as household cosmetics and chemicals, pesticides, fuels, and essential oils. The two main categories of hydrocarbons are aliphatic (straight chain structures, such as propane) and aromatic (cyclic structures, such as toluene). Hydrocarbons can also have multiple nonorganic side chains. For example, halogenated hydrocarbons usually will have at least one bromide, chloride, fluoride, or iodide moiety (eg, carbon tetrachloride). Finally, hydrocarbons are used as a solvent base for many toxic chemicals, such as insecticides, carburetor cleaner (methanol), and metals, which in turn can cause a separate distinct syndrome of poisoning. Although the range of toxicity of hydrocarbons can vary widely, the majority of human exposures are confined to petroleum distillates.

Human exposure, both intentional and unintentional, to hydrocarbons is a common problem. In 2012, U.S. poison centers reported over 36,000 exposures to hydrocarbons accounting for approximately 1.5% of all calls.1 In the previous decade, there were approximately 40,000 pediatric exposures to hydrocarbons, and almost 10% were hospitalized.2 It is estimated 9% of the United States population 12 years and older have used an inhalant for its psychoactive properties.3 Exposures to hydrocarbons are typically via inhalation, ingestion (with potential aspiration), and dermal. Inhalational exposures are typically due to either intentional abuse of volatile hydrocarbons (huffing) or household and workplace exposures. Ingestions are mostly due to accidental pediatric exposures, which also can lead to aspiration and pneumonitis. Dermal exposures are from household or workplace exposures and rarely intentional.

Pathophysiology

Acute hydrocarbons toxicity usually affects three main target organs: the lungs, the heart, and the central nervous system (CNS). Most ingestions of hydrocarbons do not lead to serious systemic toxicity but localized gastrointestinal symptoms such as abdominal pain, vomiting, and diarrhea may occur. Exceptions include halogenated or aromatic hydrocarbons, hydrocarbons containing metals or pesticides. Despite the fact that there are thousands of different types of hydrocarbons, their potential for acute toxicity depends on just a few physical properties:

- Volatility is a measure of a liquid’s ability to evaporate to a gas or vapor. Hydrocarbons with high volatility can displace alveolar oxygen and cause hypoxia. Butane and propane are examples of hydrocarbons with high volatility.
- Surface tension is the capacity for a liquid to adhere to a surface. Low surface tension, like low viscosity, enables a substance (eg, turpentine) to disperse easily and may lead to pulmonary toxicity.
- Chemical side chains or substitutions often increase potential toxicity. These include metals (eg, arsenic), halogens (eg, the chloride ions in carbon tetrachloride), and those found on aromatic structures (eg, the CH3 group in toluene).
- Lipophilicity can enhance blood brain barrier penetration resulting in CNS effects.

Pulmonary Pathophysiology

The primary target organ for direct toxicity is the lung. Fatalities after ingestion usually occur with accompanying aspiration. Hydrocarbons with high volatility, low viscosity, and low surface tension are especially dangerous (Box 152.1).4 Hydrocarbons penetrate into the lower airways, producing bronchospasm and direct injury to pulmonary alveoli and capillaries leading to an inflammatory response and pneumonitis.5-9 Hydrocarbons also impair surfactant lipid function, leading to alveolar instability and collapse, decreased compliance, and impaired gas exchange. These mechanisms lead to alveolar dysfunction, ventilation-perfusion mismatch, and hypoxemia, which can result in respiratory failure. Lipoid pneumonia can also rarely develop after hydrocarbons coalesce in alveoli and become encapsulated by fibrous tissue. This has been reported in adults siphoning gasoline and from fire-eating performances, also known as “fire-eater’s lung.”10-12

Central Nervous System Pathophysiology

Most inhalant forms of hydrocarbons cause CNS depression. Products used for recreational mood alteration include glues and adhesives, aerosols, anesthetics, cleaning agents, solvents, and gases.3 After respiratory exposure, hydrocarbons passively diffuse through the pulmonary alveoli, absorbed in blood and tissues and cross the blood brain barrier. Experimental data suggest neuropharmacological targets of hydrocarbons include glutamate/N-methyl-D-aspartate (NMDA), gamma-aminobutyric acid (GABA), dopamine and opioid receptors.3,4 Inhalation of these substances avoids hepatic first-pass metabolism and generates high concentrations in the CNS. With an isolated single exposure, these effects usually have a rapid onset of intoxication and short duration of effect. Chronic use of inhaled hydrocarbons can cause severe abnormalities in nervous system function, which include memory, attention and judgment deficits, peripheral neuropathy, cerebellar degeneration, neuropsychiatric disorders, chronic encephalopathy, and dementia. More than 50% of patients who abuse toluene for more than 10 years will have

**Cardiac Pathophysiology**

Hydrocarbons can precipitate sudden death, usually in the setting of intentional inhalation. These compounds are thought to produce myocardial sensitization to endogenous and exogenous catecholamines by inhibition of calcium signaling, which precipitates ventricular dysrhythmias and myocardial dysfunction. Anoxia is also thought to be a contributing factor. Cardiac cerebral cortical atrophy (Fig. 152.1) with histologic changes that include loss of neurons, diffuse gliosis, and axonal degeneration.4,13
Hydrocarbon solvent abuse is common and associated with various paraphernalia, such as plastic bags used for “bagging” (a method of pouring hydrocarbons in a bag or container and then inhaling deeply) and hydrocarbon-soaked cloth used for “huffing” (a method in which abusers inhale through a saturated cloth). Patients often have the distinctive odor associated with organic hydrocarbons. A characteristic coloration from spray paint (usually silver or gold as these paint colors require higher concentrations of hydrocarbon) may be present over the mouth and nose or localized angioedema may occur, resulting in a “glue-sniffer’s rash” (Fig. 152.3). These patients can also present to the emergency department (ED) with CNS intoxication with euphoria, agitation, hallucinations, confusion, or bizarre behavior. This may progress to CNS depression and seizures. In extreme cases, an individual who has inhaled solvents and then performed some type of physical exertion, such as an altercation, may suddenly collapse in cardiac arrest, likely due to cardiac sensitization by endogenous catecholamine with ensuing dysrhythmias. Drug abusers who chronically inhale hydrocarbons may be brought to medical attention—not specifically for treatment of their drug use but rather for behavioral problems or nonspecific medical symptoms caused by their abuse. The long-term chronic abuser may clinically appear similar to the chronic ethanol user, with peripheral neuropathy, cerebellar degeneration, and encephalopathy.

Another common scenario is the accidental dermal or inhaled (non-aspiration) respiratory exposure to hydrocarbons in the workplace or home. Such exposures are rarely life threatening. Most cases do not present for medical care. The few patients who present to the ED typically will be asymptomatic or have transient nonspecific symptoms, such as headache, dizziness, or nausea. Those with significant respiratory exposure may have persistent pulmonary complaints and physical findings, such as coughing, wheezing, and cyanosis. Patients with significant acute dermal exposures may have pain and evidence of chemical burns consisting of erythema, swelling, angioedema, blistering, and dermal destruction (eg, exposure to phenol).

In the absence of aspiration, large volume ingestion, or co-ingestion of another toxic substance, oral ingestion of most commonly available hydrocarbons is not associated with

dysrhythmia occurs disproportionately among those using halogenated and aromatic hydrocarbons (eg, difluoroethane). Direct skin exposure of certain hydrocarbons can cause defatting dermatitis, allergic dermatitis, or chemical burns. Intentional intravenous injection of hydrocarbons such as kerosene has led to both localized caustic and necrotic effects, and systemic effects including renal or hepatic toxicity, systemic inflammatory response syndrome (SIRS), hemolysis, seizures, pulmonary injury, cardiovascular toxicity, and death. Huffing can lead to localized increased vascular permeability, which can lead to angioedema, or localized frostbite when refrigerant is used (Fig. 152.2).

**Clinical Features**

After oral ingestion of hydrocarbons, severe poisoning is most often related to aspiration. This manifests with early respiratory symptoms, including cyanosis, coughing, grunting, noisy respirations, increased work of breathing or intractable vomiting. A patient may initially have mild symptoms and then develop tachypnea, dyspnea, bronchospasm, wheezing, rales, and fever after several hours. A change in mental status can be a manifestation of hypoxia or hypercapnia, but it is also a direct effect of the hydrocarbon itself. In extreme cases, patients may have respiratory failure requiring prehospital intubation. Various additives or solutes can produce symptoms independently (eg, seizures from camphorated hydrocarbons, cyanosis from nitrite-induced methemoglobinemia, or delayed carbon monoxide poisoning from methylene chloride). Pesticides are often dissolved in a hydrocarbon base. With pesticide exposures, it can be difficult to distinguish acute respiratory distress syndrome induced by hydrocarbon aspiration from bronchorrhea induced by organophosphate toxicity (see Chapter 157).

Hydrocarbon solvent abuse is common and associated with various paraphernalia, such as plastic bags used for “bagging” (a method of pouring hydrocarbons in a bag or container and then inhaling deeply) and hydrocarbon-soaked cloth used for “huffing” (a method in which abusers inhale through a saturated cloth). Patients often have the distinctive odor associated with organic hydrocarbons. A characteristic coloration from spray paint (usually silver or gold as these paint colors require higher concentrations of hydrocarbon) may be present over the mouth and nose or localized angioedema may occur, resulting in a “glue-sniffer’s rash” (Fig. 152.3). These patients can also present to the emergency department (ED) with CNS intoxication with euphoria, agitation, hallucinations, confusion, or bizarre behavior. This may progress to CNS depression and seizures. In extreme cases, an individual who has inhaled solvents and then performed some type of physical exertion, such as an altercation, may suddenly collapse in cardiac arrest, likely due to cardiac sensitization by endogenous catecholamine with ensuing dysrhythmias. Drug abusers who chronically inhale hydrocarbons may be brought to medical attention—not specifically for treatment of their drug use but rather for behavioral problems or nonspecific medical symptoms caused by their abuse. The long-term chronic abuser may clinically appear similar to the chronic ethanol user, with peripheral neuropathy, cerebellar degeneration, and encephalopathy.

Another common scenario is the accidental dermal or inhaled (non-aspiration) respiratory exposure to hydrocarbons in the workplace or home. Such exposures are rarely life threatening. Most cases do not present for medical care. The few patients who present to the ED typically will be asymptomatic or have transient nonspecific symptoms, such as headache, dizziness, or nausea. Those with significant respiratory exposure may have persistent pulmonary complaints and physical findings, such as coughing, wheezing, and cyanosis. Patients with significant acute dermal exposures may have pain and evidence of chemical burns consisting of erythema, swelling, angioedema, blistering, and dermal destruction (eg, exposure to phenol).

In the absence of aspiration, large volume ingestion, or co-ingestion of another toxic substance, oral ingestion of most commonly available hydrocarbons is not associated with
significant morbidity or mortality. Cough may be an early sign of pneumonitis or aspiration.

**DIFFERENTIAL DIAGNOSES**

The history of exposure to a hydrocarbon, and the route or method of that exposure is usually straightforward. Additional history and examination should focus on possible aspiration especially if the agent is ingested. Symptoms include cough, dyspnea, and shortness of breath. Signs of significant exposure include tachypnea, tachycardia, wheezing, and hypoxemia. Differential diagnosis depends upon the route of exposure, which primarily include inhalation and ingestion. CNS depressants such as ethanol, sedative-hypnotics, can mimic the altered mental status of hydrocarbon ingestion. For hydrocarbon pneumonitis, pulmonary irritants; organophosphate, salicylate, and paraquat poisonings; and viral or bacterial pneumonia may all produce a similar clinical presentation, but the history usually will lead to the correct diagnosis. In the scenario of the recreational abuser inhaling a particular agent, multiple drugs of abuse are often present somewhat confounding the clinical evaluation. Furthermore, as previously mentioned, hydrocarbons may have other constituents leading to other toxicities. Behavioral disorders and confusion can be caused by hypoxia and respiratory compromise, as well as by the drugs themselves. Hypoglycemia, electrolyte abnormalities, and trauma should be considered as an etiology of altered mentation.

**DIAGNOSTIC TESTING**

The diagnosis is usually self-evident, supported by history of exposure and chemical odor. Ideally, the offending agent is brought to the ED. The local poison control center, medical toxicologist or material safety data sheet (MSDS) may identify and verify substances containing hydrocarbons. Hydrocarbons often are vehicles for other chemicals, and other exposures should be investigated.

CHAMP is a long-standing mnemonic used to help identify hydrocarbons and their additives with systemic toxicity (Box 152.2).

Laboratory identification of hydrocarbons is difficult, time-consuming, and does not help ED management. Other laboratory tests including electrolytes, complete blood count, and liver function tests can be performed to assess for renal tubular acidosis, hypokalemia, bone marrow, or liver injury caused by various hydrocarbons. We recommend an electrocardiogram (ECG) in patients with a history of use with halogenated hydrocarbons, dysrhythmias, syncope, or hemodynamic instability. Abnormal ECG findings may include dysrhythmias (ventricular fibrillation, ventricular tachycardia, premature ventricular contractions) or QTc interval prolongation.

Patients with pulmonary symptoms should have a chest radiograph taken and be observed for at least 6 hours with a repeat chest radiograph if there is worsening of their pulmonary status.

**MANAGEMENT**

Dermal exposures to hydrocarbons can cause extensive burns, and exposed patients require early decontamination. Contaminated clothing should be removed, and the skin should be washed with soap and copious lukewarm water. Burns are treated as described in Chapters 56 and 57. Gastrointestinal decontamination with gastric lavage or activated charcoal should be avoided. Most hydrocarbons are much more toxic to lungs than to the gastrointestinal tract, and emesis may lead to aspiration and pulmonary toxicity.

Cardiac abnormalities should be treated according to standard advanced cardiac life support (ACLS)/pediatric advanced life support (PALS) resuscitation algorithms. It is also postulated that catecholamines worsen or precipitate cardiac dysrhythmias and can be treated with short acting beta blockers, such as esmolol, which are presumed to be protective. Epinephrine should be avoided in the acutely intoxicated patient for concern of precipitating an arrhythmia. Patients with any history or ECG abnormalities concerning for cardiac involvement should be monitored on cardiac telemetry until symptoms resolve.

Usually significant hydrocarbon toxicity leads to early and rapid decompensation of a patient's pulmonary, cardiac, and CNS functions. Intensive care monitoring should be used for patients with significant respiratory symptoms (respiratory distress, patient's with significant oxygen requirements, or requiring positive pressure or mechanical ventilation), cardiac involvement (arrhythmia or ECG abnormalities), or CNS depression. Patients with mild pulmonary symptoms (mild cough, minimal work of breathing, or low oxygen requirement) may be admitted to an inpatient ward for further observation. All other asymptomatic or minimally symptomatic patients should be in an observation unit with cardiac monitoring and pulse oximetry for minimum of 6 hours and until clinically well. Indications for positive pressure ventilation or mechanical ventilation include hypercarbia, severe respiratory distress, hypoxia unresponsive to noninvasive measures, and/or CNS depression. There are case reports, series, and animal models using high-frequency jet ventilation, and extracorporeal membrane oxygenation in severe cases of pneumonitis, but whether this is of benefit remains unknown. Intrapulmonary administration of surfactant has been used successfully for severe hydrocarbon pneumonitis, using elevated oxygenation index, PaO2/FiO2 ratios, or poor lung compliance as indicators for use. Corticosteroids and antibiotics have not been shown to improve outcomes and are not indicated.

In most cases of hydrocarbon ingestion or inhalation, symptomatic care along with close observation and monitoring are the cornerstones of management.

**DISPOSITION**

Exposures to known, relatively benign hydrocarbons with minimal symptoms should have a 6-hour period of observation. If no signs of pulmonary or systemic toxicity develop during the observation period and the patient has a normal 6-hour chest radiograph, the patient may be discharged to home after appropriate psychiatric clearance if indicated. If pulmonary symptoms develop (tachypnea, hypoxia) and a chest radiograph shows evidence of pneumonitis (Fig. 152.4), patients will require hospital admission for at least 24 hours until symptoms have improved. Patients with CNS depression, history of dysrhythmia, significant respiratory distress or requiring more significant respiratory support should be monitored in the intensive care unit (Box 152.3).

**BOX 152.2**

**CHAMP Mnemonic**

Camphor, can cause neurotoxicity and seizures

Halogenated hydrocarbons, can cause dysrhythmias and hepatotoxicity

Aromatic hydrocarbons, can cause bone marrow suppression and leukemia

Metals (eg, arsenic, mercury, and lead) can cause neurotoxicity

Pesticides, can cause cholinergic crises, seizures, and respiratory depression
Recreational users via inhalation of hydrocarbons should be briefly observed until clinical symptoms are improving or resolved. In most cases if the patient is asymptomatic without complaints, they may be discharged after medical clearance for drug abuse counseling. Patients with concerning hydrocarbon exposures should be managed in conjunction with a poison control center and/or a medical toxicologist.

**KEY CONCEPTS**

- Aspiration is the major toxic risk of hydrocarbon poisoning.
- Hydrocarbons may cause systemic toxicity, burns, seizures, cardiac dysrhythmias, and altered mentation depending upon agent.
- Gastrointestinal decontamination is potentially harmful in cases of hydrocarbon ingestion and is contraindicated.
- Hydrocarbon inhalant abuse can cause CNS and cardiotoxic effects.
- Symptoms of toxicity, especially aspiration, can be delayed, so asymptomatic patients should be observed for 6 hours and given clear instructions to return if symptoms develop after discharge.
- In most cases of hydrocarbon ingestion or inhalation, symptomatic care along with close observation and monitoring are the cornerstones of management. Currently, there are no specific antidotes for hydrocarbons. Patients who have or develop pulmonary symptoms should have a chest radiograph performed.

Hydrocarbons can affect many organ systems, but derangements in which organ system most commonly lead to death after hydrocarbon exposure?

A. Cardiac
B. Gastrointestinal
C. Nervous
D. Pulmonary
E. Renal

**Answer:** D. Most fatalities from hydrocarbon ingestion occur because of aspiration. Hydrocarbons cause direct lung injury, as well as displace oxygen and disrupt surfactant. Hydrocarbons can sensitize the myocardium to catecholamines, which can result in cardiac sensitization. Hydrocarbons cause few symptoms when in the gastrointestinal tract, but they can be fatal when aspirated. Any gastrointestinal complications from hydrocarbon exposure are rare unless related to aspiration potential. Chronic hydrocarbon abuse or exposure causes nervous system dysfunction, including peripheral neuropathy, cerebellar degeneration, and neuropsychiatric disorders, but typically do not result in death. Several hydrocarbons cause renal failure, particularly toluene, but rarely result in death.

**REFERENCES**

D. Toxic alcohol poisoning and acute renal failure
E. Traumatic intracranial hemorrhage

**Answer: B.** This adolescent has likely abused a hydrocarbon (such as, toluene from gold spray paint) for recreational and euphoric reasons. Aside from pulmonary toxicity from aspiration pneumonitis, you are concerned about the possibility of direct cardiotoxicity from the inhaled hydrocarbon resulting in ventricular dysrhythmias and cardiac arrest.
Inhalational exposure to systemic toxins can be covert and indolent (as in occupational exposure to irritant photochemical smog) or overt and fulminant. The circumstances of the exposure, the presence of combustion or odors, and the number and condition of victims assist in the management. Despite the array of possible toxic inhalants, identification of a specific inhalant is generally unnecessary because therapy is based primarily on the clinical manifestations (Table 153.1).

SIMPLE ASPHYXIANTS

Principles of Toxicity

Simple asphyxiants are inert and produce toxicity only by displacement of oxygen and lowering of the fraction of inspired oxygen (Fio₂). Exposed patients remain asymptomatic if the Fio₂ is normal. Carbon dioxide and nitrogen are exceptions in that both can produce narcosis at elevated partial pressures, even though their predominant toxicological effect is simple asphyxiation. Since the introduction of catalytic converters, most deaths from the intentional inhalation of automotive exhaust result from simple asphyxiation, due to hypoxia, and not from carbon monoxide (CO) poisoning.¹

Clinical Features

Acute effects occur within minutes of onset of hypoxia and are the manifestations of ischemia. A fall in the Fio₂ from normal, 0.21 (ie, 21%), to 0.15 results in autonomic stimulation (eg, tachycardia, tachypnea, and dyspnea) and cerebral hypoxia (eg, ataxia, dizziness, incoordination, and confusion). Dyspnea is not an early finding, because hypoxemia is not nearly as potent a stimulus to the medullary respiratory center as are hypercarbia and acidemia. Lethargy from cerebral edema occurs as the Fio₂ falls below 0.1 (10%), and life is difficult to sustain at an Fio₂ below 0.06 (6%). Because removal from exposure terminates the simple asphyxiation and allows restoration of oxygenation and clinical improvement, most patients present with resolving symptoms. However, failure to improve suggests complications of ischemia (eg, seizures, coma, and cardiac arrest) and is associated with a poor prognosis.

Differential Diagnosis

Because the presenting complaints offered by most exposed patients are nonspecific (eg, dizziness, syncope, and dyspnea), the differential diagnosis is extensive. A consistent history, particularly of a setting in which asphyxia is expected to occur, an appropriate spectrum of complaints, and a rapid resolution on removal from exposure are generally sufficient to establish the diagnosis.

Diagnostic Testing

Minimally symptomatic or asymptomatic patients do not require chest radiography or arterial blood gas (ABG) analysis. There is no role for toxicology testing unless the asphyxiation was an act of deliberate self-harm, in which case we recommend selected screening for acetaminophen and any other relevant toxin implicated by history, physical examination, or observation. A definitive diagnosis ultimately requires scene investigation by a trained and suitably outfitted team. Determination of the exact nature of the gas is of limited clinical value but may have important public health implications.

Management

Management rarely requires specific therapy other than removal from exposure, supportive care, and administration of supplemental oxygen. Neurologic injury or cardiorespiratory arrest should be managed with standard resuscitation protocols. Psychiatric consultation is indicated when the exposure was an act of deliberate self-harm.

Disposition

Patients with manifestations of mild asphyxia who recover after removal from the exposure can be discharged after 6 hours of observation if they are asymptomatic or minimally symptomatic and improving. Patients at risk for complications of hypoxia, such as those presenting with significant signs or symptoms (eg, coma, chest pain, electrocardiogram [ECG] changes) or with exacerbating medical conditions (eg, cardiac disease), should be observed for 24 to 48 hours for the development or progression of post-hypoxic complications.

PULMONARY IRRITANTS

Principles of Toxicity

The pulmonary irritant gases are a large and diverse group of agents that produce a common toxicological syndrome when they are inhaled in moderate concentrations. Although many of these gases can be found in the home, significant poisoning from consumer products is uncommon because of restrictions designed to reduce their toxicity. However, catastrophes such as the 1984 release of methyl isocyanate in Bhopal, India, which resulted in more than 2000 fatalities and 250,000 injuries, remain as an environmental risk. On a different scale, industrialization has increased ambient concentrations of sulfur dioxide, ozone, and oxides of nitrogen. These irritant gases frequently exacerbate chronic pulmonary disease.

Irritant gases dissolve in the respiratory tract mucus and alter the air-lung interface by invoking an irritant or inflammatory response.² When these gases are dissolved, most of them produce an acid or alkaline product, but several generate oxygen-derived free radicals that produce direct cellular toxicity (Fig. 153.1). The clinical effects of pulmonary irritants can be predicted by their water solubility (see Table 153.1).

Clinical Features

Highly water-soluble gases rapidly impact the mucous membranes of the eyes (lacrimation) and upper airway (nasal burning, cough).
Although their pungent odors and rapid onset of symptoms tend to limit significant exposure, massive or prolonged exposure can result in life-threatening laryngeal edema, laryngospasm, bronchospasm, or acute respiratory distress syndrome (ARDS). In contrast, because poorly water-soluble gases do not readily irritate the mucous membranes at low concentrations and some have pleasant odors (eg, phosgene’s odor is similar to that of hay), prolonged breathing in the toxic environment allows time for the gas to reach deep into the alveoli. Even moderate exposure causes delayed irritation of the lower airway, alveoli, and parenchyma after a 2- to 24-hour delay after exposure. Initial effects may be mild, only to progress to overt respiratory failure and ARDS during the ensuing 24 to 36 hours. Gases with intermediate water solubility tend to produce syndromes that are a composite of the clinical features manifested with the other gases, depending on the extent of exposure. Massive exposure is most often associated with rapid onset of upper airway irritation and more moderate exposure with delayed onset of lower airway symptoms.

**Differential Diagnosis**

The typical symptoms of pulmonary exposure to irritant gas are bronchospasm, cough, a sensation of chest tightness, and acute conjunctival irritation, all of which may occur following allergen exposure, but the history generally confirms the exposure to the irritant. History may be particularly important if the patient

Although their pungent odors and rapid onset of symptoms tend to limit significant exposure, massive or prolonged exposure can result in life-threatening laryngeal edema, laryngospasm, bronchospasm, or acute respiratory distress syndrome (ARDS). In contrast, because poorly water-soluble gases do not readily irritate the mucous membranes at low concentrations and some have pleasant odors (eg, phosgene’s odor is similar to that of hay), prolonged breathing in the toxic environment allows time for the gas to reach deep into the alveoli. Even moderate exposure causes delayed irritation of the lower airway, alveoli, and parenchyma after a 2- to 24-hour delay after exposure. Initial effects may be mild, only to progress to overt respiratory failure and ARDS during the ensuing 24 to 36 hours. Gases with intermediate water solubility tend to produce syndromes that are a composite of the clinical features manifested with the other gases, depending on the extent of exposure. Massive exposure is most often associated with rapid onset of upper airway irritation and more moderate exposure with delayed onset of lower airway symptoms.
Diagnostic Testing

Inhalation of respiratory irritants may affect the upper airway, the lower airways and lungs, or both. Upper airway evaluation proceeds as described in the following Management section. Radiographic and laboratory studies are not useful in the evaluation of upper airway symptoms.

Oxygenation and ventilation are assessed by serial chest auscultation, pulse oximetry, and continuous capnography. Chest radiography is indicated for patients presenting with cough, dyspnea, hypoxia, or abnormal findings, such as rales or wheezes, on physical examination. ABGs are reserved for patients who are more severely symptomatic, have hypoxia, or do not improve readily with appropriate therapy.

In general, it is neither possible nor necessary to test for the specific agent. There are no clinical tests that will differentiate the irritant to which a patient was exposed, although testing at the site by public health authorities may be performed for epidemiologic purposes. Knowing that an agent was highly water soluble will shorten the observation period for symptom development, whereas patients exposed to poorly water soluble agents will require a more prolonged period of observation.

Management

Patients with no upper airway symptoms, normal voice, and no evidence of irritation (erythema) on examination of the oral pharynx require no further upper airway evaluation, but should be reexamined if symptoms or signs develop after the initial examination. Those with evidence of severe tissue irritation, such as oral or tongue edema, altered voice (raspy or muffled), or significant odynophagia or dysphagia should undergo early intubation, because progression of these injuries can be expected. Patients with significant erythema or pain in the oropharynx or nasopharynx and those with any evidence of alteration of voice, dysphagia or odynophagia, or stridor require early examination by laryngoscopy. Laryngoscopy may be performed using a flexible laryngoscope or rigid video or conventional laryngoscopy with appropriate topical anesthesia and sedation as indicated (see Chapter 1). Patients with evidence of mild irritation of the larynx or supralaryngeal area (erythema, no edema, normal glottis) may be observed. Those with more severe findings considered not to require early intubation, such as erythema with mild edema, should undergo repeat examination 30 to 90 minutes after the initial examination or earlier, if symptoms or signs are worsening.

Bronchospasm generally responds to inhaled beta-adrenergic agonists in usual doses. There is no indication for ipratropium or a corticosteroid unless the patient has known underlying reactive airways disease. 

Patients exposed to chlorine or hydrogen chloride gas receive symptomatic relief from nebulized 2% sodium bicarbonate solution. This solution is prepared by diluting a given volume of standard 8.4% sodium bicarbonate solution with three equivalent volumes of sterile water, and administering it with standard nebulizer equipment. There are no studies on the recommended dosing regimen, but if successful after its first use, providing it every 30 minutes as needed for symptom relief, for up to 6 hours, should be safe. Nebulized bicarbonate will not alter the inflammatory cascade, however, so it will not have significant effect on the progression of pulmonary injury.

ARDS, if identified, is managed as described in Chapters 22 and 67.

Disposition

Patients exposed to highly water-soluble gases (see Table 153.1) can be discharged if they are asymptomatic or symptoms are minimal and improving. After exposure to intermediate or poorly water-soluble gases, asymptomatic patients should be observed for increasing dyspnea for 6 hours before final disposition. Patients with prolonged gas exposure or exposure to highly concentrated gases, which may occur in a closed space, even if asymptomatic, or those in high-risk situations (eg, underlying pulmonary disease, extremes of age, and poor follow-up) should be observed in an inpatient setting or observation unit for 24 hours. Patients with upper airway findings on examination are observed in the emergency department (ED) or an intensive care unit (ICU) until there is clear evidence that the process is subsiding. All discharged patients should receive instructions for signs and symptoms of pulmonary deterioration.

SMOKE INHALATION

Principles of Toxicity

Annually, approximately 4000 people are injured or die in residential fires in the United States. Many of these casualties do not suffer serious cutaneous burns but rather die of smoke inhalation. This is a variant of irritant injury in which heated particulate matter and adsorbed toxins injure normal mucosa. In addition, CO and cyanide are systemic toxins often considered along with the smoke inhalation syndrome because of their common origin.

Even at temperatures between 350° and 500° C, air has such a low heat capacity that it rarely produces lower airway damage. However, the greater heat capacity of steam (approximately 4000 times that of air) or heated soot suspended in air (ie, smoke) can transfer heat and cause injury deep within the respiratory tract.

The nature of the fuel determines the composition of its smoke, and because fires involve variable fuels and burning conditions, the character of fire smoke is almost always undefined to the clinician. Irritant toxins produced by the fire are adsorbed onto carbonaceous particles that are deposited in the airways and damage the mucosa through mechanisms similar to those of the irritant gases.

Clinical Features

Thermal and irritant-induced laryngeal injury may produce cough, voice alteration, or stridor, but these findings are often delayed. Soot and irritant toxins in the airways can produce early cough, dyspnea, and bronchospasm. Subsequently, a cascade of airway inflammation results in ARDS with failure of pulmonary gas exchange. The time between smoke exposure and the onset of clinical symptoms is highly variable and dependent on the nature of the exposure. Deaths that occur rapidly after exposure are caused by asphyxia, airway compromise, or metabolic poisoning (eg, CO). Singed nasal hairs and soot in the sputum suggest substantial exposure, but significant exposure and injury can occur with neither of these being present.

Differential Diagnosis

With the obvious exposure history, the differential diagnosis is limited. Although it is often unclear whether inhalational injuries are thermal or irritant, the differentiation is clinically irrelevant. Concomitant physical injuries such as burns or trauma may complicate the metabolic picture.
Diagnostic Testing

Airway patency should be evaluated early. Airway management is as described earlier for inhaled pulmonary irritants. If evidence of significant airway exposure is present, such as carbonaceous sputum or hoarse voice, the airway should be examined by rigid or flexible laryngoscopy, and secured if signs of injury or compromise are noted. Pulmonary injury is assessed through auscultation and chest radiography for signs of alveolar filling or hyperinflation. Oxygenation should be assessed by co-oximetry, because blood gas analysis and pulse oximetry may be inaccurate in CO-poisoned patients (see discussion in the Carbon Monoxide section later). Co-oximetry will provide a blood carboxyhemoglobin (COHb) level, and we recommend testing for every patient, unless the smoke exposure was brief and in an open space. Metabolic acidosis, particularly when serum lactate concentration is greater than 10 mmol/L, suggests concomitant cyanide poisoning.

Management

The acute management of smoke inhalation is identical to that of other irritant inhalational injuries. Early assessment of the airway and early intubation, as indicated, are critical because deterioration may be occult and rapid. Patients with no upper airway symptoms, normal oropharyngeal and nasopharyngeal examination, no voice alteration, and normal swallowing may be observed and reevaluated if symptoms, even mild symptoms, develop. Patients with symptoms or findings, though, are evaluated early by rigid or flexible laryngoscopy. Simply observing these patients for deterioration can result in airway compromise requiring rapid and, by then, difficult airway intervention. Despite a lack of evidence supporting their effectiveness, inhaled beta-adrenergics are widely used for patients with dyspnea or wheezing. Because these may provide benefit with little likelihood of harm, we recommend at least one dose of a beta-adrenergic agonist for patients with symptoms of bronchospasm. Both subjective (patient reported and findings on auscultation) and objective (spirometry) assessment may be used to determine whether these agents appear to benefit a particular patient and guide use of additional doses. Optimal supportive care and maintenance of adequate oxygenation (eg, suctioning and pulmonary toilet) are the most important aspects of care. Bronchoscopy with bronchoalveolar lavage is frequently recommended to clear debris and toxins from the distal airways. We do not recommend the use of corticosteroids, by inhalation or systemically, because there is no evidence of benefit and they are potentially harmful in patients with cutaneous burns. Ibuprofen, antioxidants, exogenous surfactant, and high-frequency ventilation yield variably improved survival in experimental and clinical trials; none is considered standard care. Antibiotics should be used only in patients with suspected infection.

Disposition

Patients who are intubated should be admitted to the ICU or burn unit, depending on the extent of the cutaneous burns or respiratory tract injury. Patients with upper airway symptoms or signs, but without concerns for airway loss, should undergo repeat airway examination for 6 hours, preferably in an ICU. Patients with prolonged closed-space exposure or lower airway findings, such as rales or carbonaceous sputum, should be admitted to an ICU and observed for at least 24 hours while assessing for the development of signs of lower respiratory tract injury. Transfer to a higher level of care at another hospital or to a burn center should be based on local resources, consultation with the specialty center, an assessment of the risks of transfer, and existing protocols (see Chapter 56).

Principles of Toxicity

Instead of directly affecting the airway and lungs, these poisons cause effects at the cellular level. Hydrogen cyanide is a gas with many commercial uses, particularly in synthetic fiber manufacture and fumigation. Gaseous hydrogen cyanide is occasionally noted to have the odor of bitter almonds. Cyanide in its salt form (e.g., sodium or potassium) is important in the metallurgy (e.g., jewelry) and photography and is much safer to work with because of its low volatility. When cyanide salts are dissolved in water, hydrogen cyanide can leave the surface, particularly under acidic conditions. Cyanide is metabolically released in vivo from precursors (cyanogens) such as amygdalin, found in apricot and other Prunus species pits, and from nitriles, a group of chemicals with many commercial uses.

Hydrogen sulfide poisoning most often occurs in petroleum refinery and sewage storage tank workers. A recent Internet-derived means of suicide involves generation of hydrogen sulfide from sulfur-containing products, such as detergent, mixed with acids in an enclosed space, such as an automobile. On occasion, well-intentioned but ill-prepared rescuers become victims, emphasizing the need for proper training and equipment. Hydrogen sulfide has a noxious odor similar to rotten eggs, which becomes unnoticed with extremely high concentrations or prolonged exposure (a process called olfactory fatigue).

Gaseous cyanide is rapidly absorbed after inhalation and is immediately distributed to the oxygen-using body tissues. Inhibition of oxidative metabolism by binding to cytochrome c oxidase (or Complex IV) of the electron transport chain within mitochondria occurs within seconds. The poisoned tissue rapidly depletes its adenosine triphosphate reserves and ceases to function (Fig. 153.2). Cyanide has no evident effect on other oxygen-binding enzyme systems, most notably hemoglobin. This is probably explained by the oxidation state of its iron moiety; cyanide binds only to oxidized iron (Fe3+), whereas deoxyhemoglobin contains reduced iron (Fe2+).

Hydrogen sulfide exerts its toxic effects both as a pulmonary irritant and as a cellular poison. Its deadly metabolic effects are produced by a mechanism identical to that for cyanide. However, hydrogen sulfide's spontaneous dissociation from the mitochondria is rapid, allowing many patients to survive after brief exposure.

Clinical Features

Tissue hypoxia occurs within minutes, with the exact onset dependent on the route, dose or concentration, and nature of the exposure. Dysfunction of the heart and the central nervous system—the organ systems most sensitive to hypoxia—is characteristic of cyanide poisoning, manifested as coma, seizures, dysrhythmias, and cardiovascular collapse. Metabolic acidosis develops as a result of diffuse cellular dysfunction and is associated with an elevated serum lactate concentration. Cyanosis is not a characteristic clinical finding. Given the extreme toxicity of cyanide, mild acute poisoning is uncommon. Patients with acute hydrogen sulfide poisoning have similar clinical manifestations, although many recover by the time of arrival in the ED.

Because cyanide and hydrogen sulfide prevent tissue extraction of oxygen from the blood, the oxygen content of venous blood remains high, approaching that of arterial blood. Clinically, this may appear as the “arterialization” or brightening of venous blood to resemble arterial blood. A comparison of the measured venous and arterial oxygen contents may assist in the diagnosis of cyanide poisoning. A low arterial-venous oxygen difference is suggestive
of cyanide poisoning but its absence is neither exclusionary nor its presence pathognomonic for the diagnosis.

Patients surviving cyanide or hydrogen sulfide poisoning may have persistent or delayed-onset neurologic syndromes identical to those noted in patients with CO poisoning or cardiac arrest.

Differential Diagnosis

In practice, rapid cardiovascular collapse, hypotension, bradycardia, ventricular dysrhythmias, and seizures in a fire victim should suggest cyanide poisoning, severe CO poisoning, or both. In patients without an exposure history, the differential diagnosis is vast and includes CO poisoning, asphyxiants, cardiotoxins, cardiac dysfunction (dysrhythmia, myocardial infarction), and sepsis.

Diagnostic Testing

Unlike with CO poisoning, pulse oximetry and ABG analysis are accurate in cases of isolated cyanide or hydrogen sulfide poisoning. An increased anion gap metabolic acidosis and elevated serum lactate concentration are usually present. A lactate concentration greater than 10 mmol/L in a fire victim is highly predictive of cyanide poisoning. CO and cyanide are fellow travelers, so an elevated COHb level in a fire victim warrants consideration of concomitant cyanide poisoning. The presence of severe clinical findings with a low COHb level is particularly concerning for cyanide poisoning. The result of a blood cyanide determination is usually too delayed to be of use in the ED, but it can be useful for confirmation and documentation purposes. Technology exists for immediate cyanide determination but is not widely available.

Testing for hydrogen sulfide is not clinically available. For confirmation and documentation purposes, Technology exists which is usually too delayed to be of use in the ED, but it can be useful.

Management

The diagnosis of cyanide poisoning usually cannot be confirmed rapidly, and therapy is almost always empirical. Treatment should not be delayed pending the COHb level or other laboratory tests in patients with suspected acute cyanide poisoning. Patients removed from a fire environment who have cardiovascular instability, altered mental status, or a serum lactate greater than 10 mmol/L should receive cyanide treatment regardless of the COHb concentration.
Hydrogen Cyanide

The accepted goal of therapy is to reactivate the cytochrome oxidase system by providing an alternative binding site for the cyanide ion. There are two types of antidotal therapy for cyanide. The preferred antidote is hydroxocobalamin, which takes advantage of the high affinity of cobalt for cyanide. On binding of cyanide, cyanocobalamin, or vitamin B12, is formed. The initial dose is 5 g intravenous (IV) over 15 minutes for adults and 70 mg/kg IV for children, up to an adult dose, and can be repeated once if an incomplete response is noted. Thiosulfate (see later), 12.5 g, can be administered concomitantly over 10 minutes through a separate IV. The known adverse effects of hydroxocobalamin are mild and include hypertension in those not cyanide poisoned and a bright red discoloration of the patient’s skin. Inexperienced clinicians often mistake this side effect as an “allergic” reaction to the drug. The drug’s red color can interfere with certain spectrophotometric laboratory tests, including COHb and possibly serum lactate, and blood samples should be obtained before the administration of the first dose of hydroxocobalamin.10

The cyanide antidote kit is an alternative therapy for cyanide toxicity. The cyanide antidote kit produces a high-affinity source of ferric ions (Fe3+3) for cyanide to bind. The kit has three components (amyl nitrite, sodium nitrite, and sodium thiosulfate), and although the best results are likely to be attained when the entire kit is used, this may be impractical or dangerous, particularly for nonhospital providers. Because animal models and clinical evidence in humans demonstrate that sodium thiosulfate alone (the “third” component of the kit), in combination with oxygen, offers substantial protection, this should be the initial therapy administered for delayed neuropsychiatric findings. Antidotes should not completely replace other resuscitation measures, including high-flow oxygen and removal of the patient from the source of exposure.

Methemoglobin (MetHb) formation results from first two components of the kit. Inhaled amyl nitrite and IV sodium nitrite are both effective, but amyl nitrite should be administered to patients only before IV access. Caution should be taken to minimize the provider’s exposure to the volatile amyl nitrite because dizziness, hypotension, or syncope may occur. The dose of sodium nitrite for a previously healthy adult is 300 mg (10 mL of a 3% solution) given during 2 to 4 minutes, and dosing instructions for anemic patients and children are supplied with the kit. Cyanide has a high affinity for MetHb and readily leaves cytochrome oxidase to form cyanmethemoglobin, which is metabolically inactive. Additionally, the nitrates are vasodilators, and this may be mechanistically important in their therapeutic effect by enhancing blood flow to the liver for clearance. However hypotension may complicate a rapid infusion.

Both free serum cyanide and cyanmethemoglobin are converted by sulfur transferase (rhodanese) to thiocyanate, which is renally eliminated. Because the rate of rhodanese function increases with the availability of sulfur donor, the third component of the antidote kit is the sulfur-containing compound sodium thiosulfate. The adult dose is 12.5 g IV, which is provided as 50 mL of a 25% solution (2 mL/kg of 25% sodium thiosulfate up to an adult dose in children). In general, few if any adverse effects are associated with proper doses. The nitrite components of the cyanide antidote kit should be avoided in fire victims with known or suspected simultaneous CO and cyanide poisoning because both CO and MetHb reduce oxygen delivery to the tissues. The use of the thiosulfate component alone in this subset of patients is recommended (Box 153.1).

There are insufficient clinical data to fully support the use of one cyanide antidote over the other. However, we recommend hydroxocobalamin, which is largely replacing the cyanide antidote kit because of its ease of use and presumed superior safety in CO-poisoned fire victims.11 Direct comparison to thiosulfate alone in this population has not been and likely never will be performed, but animal models suggest that hydroxocobalamin is superior.12 When possible, we recommend administering both hydroxocyanocobalamin and thiosulfate, with the priority given to hydroxocyanocobalamin, and never giving them through the same IV.

Hydrogen Sulfide

Because the bond between hydrogen sulfide and cytochrome oxidase is rapidly reversible, removal from exposure and standard resuscitative techniques are usually sufficient to reverse hydrogen sulfide toxicity. Use of the nitrite portion of the cyanide antidote kit is suggested to create MetHb for patients with severe or prolonged toxicity. Sodium thiosulfate is unnecessary because hydrogen sulfide is not detoxified by rhodanese. There is no defined role for hyperbaric oxygen (HBO) therapy in cases of hydrogen sulfide toxicity.

Disposition

Patients with symptomatic cyanide or hydrogen sulfide poisoning should be admitted to a critical care unit and observed for complications of tissue hypoxia. These patients should also be evaluated for delayed neuropsychiatric findings.

CARBON MONOXIDE

Principles of Toxicity

CO is the most common cause of acute poisoning death in developed nations and the most common cause of fire-related death.13 CO is generated through incomplete combustion of virtually all carbon-containing products. Structure fires (eg, wood), clogged vents for home heating units (eg, methane), and use of gasoline-powered generators indoors are examples of the myriad means through which patients are poisoned by CO. Appropriate public health authorities (eg, fire department and Department of Health officials) should be informed immediately about any potential public health risks that are identified during the care of a CO-exposed patient.

---

**BOX 153.1**

**Cyanide Antidotes**

**HYDROXOCOBALAMIN**
- Adults: 5 g IV over 15 minutes
- Children: 70 mg/kg up to 5 g

**CYANIDE ANTIDOTE KIT**

1. **MetHb inducers**
   - Amyl nitrite (intrahospital, prehospital) or
   - Sodium nitrite (NaNO2) 3% solution IV over 2 to 4 minutes IV
   - Adults: 10 mL (300 mg)
   - Children: See labeling information with kit

2. **Cyanide detoxification**
   - Sodium thiosulfate (NaS2O3) 25% solution IV
   - Adults: 50 mL (12.5 g)
   - Children: 1.65 mL/kg up to 50 mL

**IV**, Intravenous; **MetHb**, methemoglobin.

*A second dose may be administered in patients with an incomplete response.

1 Withhold nitrites if blood carboxyhemoglobin (COHb) is suspected to be present (eg, fire victims).
CO interacts with deoxyhemoglobin to form COHb, which cannot carry oxygen. Hemoglobin binds CO tightly and forms a complex that is only slowly reversible. This allows the exposed individual to accumulate CO, even with exposure to low ambient concentrations. Although binding of hemoglobin is historically described as the mechanism of CO poisoning, it is relevant only in profoundly CO-poisoned patients because a simple reduction in oxygen-carrying capacity due, for example, to anemia would not cause similar symptoms. However, for pregnant patients, the fetus is at increased risk, because it is relatively hypoxic compared with the mother. Additionally, CO shifts the oxyhemoglobin dissociation curve to the left in such a way that even if oxygen is bound to hemoglobin, its unloading to tissues is impaired. In muscle, CO binds myoglobin, preventing its normal function, and this probably explains the development of rhabdomyolysis.

Most importantly, CO affects cellular oxygen use at the tissue level. CO, similar to cyanide, inhibits the final cytochrome complex involved in mitochondrial oxidative phosphorylation. This results in a switch to anaerobic metabolism and ultimately in cellular death.

Delayed-onset neurologic complications may be a manifestation of the hypoxic insult, and reperfusion injury and lipid peroxidation related to platelet-induced nitric oxide release may play a significant role. By alteration of the platelet-associated nitric oxide cycle, the microvascular endothelium of the central nervous system undergoes free radical–mediated injury, resulting in localized inflammation and dysfunction. Animal models and human reports suggest that loss of consciousness during CO exposure is a risk factor for the development of delayed neurologic sequelae.

**Clinical Features**

Severe CO toxicity and cyanide poisoning have identical clinical presentations of chemical asphyxia: altered mental status, including coma and seizures; extremely abnormal vital signs, including hypotension and cardiac arrest; and metabolic acidosis. Unlike cyanide poisoning, however, mild CO poisoning occurs frequently, with headache, nausea, vomiting, dizziness, myalgia, and confusion as common presenting complaints. The neurological assessment in these patients may yield normal findings or may demonstrate focal findings or subtle perceptual abnormalities. The often-touted cherry-red skin color in patients with cyanide or CO poisoning is a postmortem finding and is not noted in living patients.

Delayed neurologic sequelae is a well-documented phenomenon after CO exposure; the frequency varies from 12% to 50%, depending on the definition and the sensitivity of the test used for their detection. Patients have a variety of neurologic abnormalities after an asymptomatic period, ranging from 2 to 40 days. The delayed neurologic effects can be divided into those with readily identifiable neurologic syndromes (eg, focal deficits and seizures) and those with primarily psychiatric or cognitive findings (eg, apathy and memory deficits). Although the delayed neuropsychiatric sequelae require formal neuropsychiatric testing to be detected, the impact of these abnormalities on the patient’s daily function may be significant. Risk factors that predict the development of delayed neurologic sequelae include extremes of age and loss of consciousness. Because most CO-poisoned patients reaching the ED survive with minimal intervention, prevention of delayed neurologic and neuropsychiatric sequelae is a major goal of therapy.

**Differential Diagnosis**

Mild to moderate CO poisoning is a difficult diagnosis to establish clinically, and patients are easily misdiagnosed as having a benign headache syndrome or viral illness. CO poisoning should be suspected in patients with persistent or recurrent headache, especially if a group of people have similar symptoms or if the headache improves soon after the person leaves an exposure site.

Patients with severe CO poisoning may present with coma or cardiovascular collapse, both of which have a broad toxicologic, metabolic, infectious, medical, and traumatic differential diagnosis. The medical history, physical examination, and standard laboratory testing are easily able to exclude many of these diagnoses. Given the relatively protean manifestations of CO poisoning and the potentially serious consequences of misdiagnosis, particularly if the patient returns to the contaminated environment, we recommend specific measurement of CO by co-oximetry of an arterial or venous blood sample when the clinician considers CO poisoning as a cause for the patient’s presentation.

**Diagnostic Testing**

Suspicion of CO poisoning relies on the history and physical examination findings. Co-oximetry, an inexpensive and readily available spectrophotometric laboratory method that can distinguish between normal hemoglobin and COHb (and MetHb), confirms exposure to CO. Other laboratory tests only exclude other diagnoses. Severity of poisoning may not correlate with COHb levels because prolonged exposure to low levels can be fatal with a low measured COHb, but a brief, high-concentration exposure can produce a high COHb level with minimal symptoms.

The standard blood gas (ABG or venous blood gas [VBG]) analysis is a poor screening test for CO poisoning other than to identify the presence of a metabolic acidosis and a normal partial pressure of oxygen (Pao2). CO decreases oxygen bound to hemoglobin but does not affect the amount of oxygen dissolved in blood. Because the Pao2, a measure of dissolved oxygen, is normal in patients with CO poisoning, the calculated oxygen saturation will be normal even in the presence of significant CO poisoning. Most pulse oximeters are unable to detect CO poisoning because COHb essentially is misinterpreted as oxyhemoglobin. Newer pulse co-oximeters are capable of noninvasively detecting COHb as well as methemoglobinemia, but these instruments are not yet in common use.

**Management**

Treatment begins with oxygen therapy, which serves two purposes. First, the half-life of COHb is inversely related to the Pao2; it can be reduced from approximately 5 hours on room air to 1 hour by providing supplemental 100% oxygen. HBO therapy (at 3 ATA) further reduces the half-life to approximately 30 minutes. Unfortunately, alteration of the kinetics of COHb is relevant only to patients with extremely elevated COHb levels (eg, 50%). Even then, only a minority of patients can be treated sufficiently rapidly for the HBO to be life saving. Second, a sufficient Pao2 can be achieved with HBO to sustain life in the absence of adequately functioning hemoglobin, but this is helpful only when the COHb is extremely elevated. Thus, the primary indication for HBO is not to prevent mortality but rather to prevent delayed neurologic sequelae.

There is controversy regarding the benefit of HBO because the effect is not immediate (as with life and death) and outcome assessment requires close follow-up and sophisticated testing. Several evidence-based reviews have asserted only a limited role for HBO, although this conclusion is disputed. Evidence suggests that HBO helps prevent the development of delayed neuropsychiatric and neurologic sequelae after CO poisoning, with a decrease of delayed neurologic sequelae from approximately 12% to less than 1% with HBO. When HBO administration is delayed
more than 6 hours after exposure, its efficacy appears to decrease, suggesting the need for rapid implementation. A randomized, double-blind study found that HBO therapy was superior to normobaric oxygen therapy at reducing the incidence of delayed neurologic sequelae at both 6 weeks and 1 year after poisoning. However, another found no benefit of HBO on the development of delayed neurologic sequelae compared with extensive normobaric oxygen. In the latter study, however, the majority of patients were suicidal and possibly depressed, which would interfere with performance on the neuropsychiatric testing needed to differentiate the two groups of patients. Another trial found that in comatose patients, one HBO session was superior to two sessions; however, in patients with transient loss of consciousness (ie, syncope), outcome after HBO therapy was equivalent to 6 hours of normobaric oxygen therapy.

Given the implications of poor tissue oxygenation with COHb and the relative safety of HBO, a patient with a neurologic abnormality or cardiovascular instability (eg, syncope, altered mental status, myocardial ischemia, and dysrhythmias) is a candidate for HBO (Box 153.2). This should be tempered by the need for transport, often over long distances, for HBO therapy to be obtained. The decision about HBO therapy should not be strictly based on the COHb level, which correlates only weakly with toxicity. For example, patients with prolonged low-level exposure have a “soaking” phenomenon, in which extremely high tissue concentrations of CO occur with low COHb levels. Thus, patients with consequential clinical findings that are considered to be related to CO poisoning should receive HBO, even though their COHb level is relatively low.

In addition to use of HBO in patients with obvious signs of tissue hypoxia or syncope, we recommend referral for HBO for asymptomatic patients with a COHb level of 25%. The decision to perform HBO therapy should be made in the context of transport and other medical requirements, including need for transfer to a burn center. Where doubt remains, consultation with a medical toxicologist, poison center, or the HBO treatment specialist will guide decision-making. Because fetal CO poisoning is associated with dysfunction and death and HBO therapy appears to be safe in pregnancy, we recommend HBO therapy in a pregnant woman with a COHb level of 15% or greater regardless of symptoms. Further study is still needed to define the optimal duration, pressure, and frequency, as well as the cost-benefit and risk-benefit relationships of HBO therapy. At this time, discussion with a regional HBO center or poison control center is advisable. Patients with elevated COHb levels who do not require HBO should be treated with normobaric oxygen delivered by a tight-fitting non-rebreather face mask until the symptoms resolve and the COHb levels fall to normal.

**Simultaneous Carbon Monoxide and Cyanide Poisoning (Fire Victims)**

Concurrent toxicity from CO and cyanide is widely reported and a major factor in the mortality associated with smoke. Smoke inhalation victims who present with coma and metabolic acidosis can have severe CO poisoning, cyanide poisoning, or both. Nitrite-induced methemoglobinemia, which further reduces the tissue oxygen delivery, may be detrimental to patients with elevated COHb levels or otherwise impaired oxygen delivery.

Sodium thiosulfate, administered without nitrites, or hydroxocobalamin should be given to all smoke inhalation victims with coma, hypotension, severe acidosis, or cardiovascular collapse in whom cyanide poisoning cannot be rapidly excluded.

**Disposition**

The decision to transfer a patient to an HBO facility should consider the time delay to therapy, patient issues (eg, burns and age), and potential transport-related complications. Patients with minor clinical effects that resolve can be discharged with follow-up, and those with signs of end organ effects, such as chest pain or altered mental status, if not transferred for HBO, should be admitted for observation. All patients exposed to CO require close follow-up for delayed neurologic sequelae.

### KEY CONCEPTS

- An asphyxiant is any gas that displaces sufficient oxygen from the breathable air. Treatment consists of removal from exposure, supplemental oxygen, and supportive care.
- Highly water-soluble gases produce rapid irritation and predominantly upper respiratory tract symptoms, such as airway irritation. Poorly water-soluble gases often produce delayed lower respiratory tract findings, such as bronchospasm or acute respiratory distress syndrome (ARDS).
- CO poisoning is confirmed by co-oximetry measurement. Cyanide poisoning is treated empirically when cardiovascular instability (eg, hypotension), altered mental status, or a serum lactate greater than 10 mmol/L are present in a fire victim.
- Hydroxocobalamin is the preferred antidote for most cyanide poisoned patients due to its efficacy, ease of use, and safety in patient with concomitant CO poisoning. Sodium thiosulfate may be administered concomitantly and may provide additional benefit.
- Patients with hydrogen sulfide poisoning generally respond to removal from exposure and ventilatory support.
- Normobaric oxygen therapy is sufficient for many patients with CO poisoning, but we recommend consultation with a hyperbaric oxygen (HBO) facility, poison control center, or medical toxicologist for consideration of HBO therapy for patients with a COHb greater than 25% or any new neurologic or cardiovascular abnormality.

Chapter 153: Questions & Answers

153.1 A laboratory worker is brought to the emergency department (ED) after being found unconscious. His colleague reports that the patient was found with his oxygen mask off while working in a room filled with carbon dioxide. The patient is now awake but reports feeling tired and confused. He has no other complaints. His vital signs and physical examination are normal. What toxin-specific diagnostics test should be ordered for this patient?

A. Carboxyhemoglobin (COHb)
B. Chest radiograph
C. Electrocardiogram
D. Methemoglobin (MetHb)
E. No tests are indicated

Answer: E. Carbon dioxide is primarily a simple asphyxiant, meaning that its major consequential adverse effects stem from its displacement of oxygen in the lungs. Once patients are removed from the source, they generally recover completely. Patients should be observed until this time. COHb measurement would be indicated if there is a suspicion of carbon monoxide (CO) exposure. Chest radiographs should be ordered if patients have pulmonary complaints after an unknown exposure. Electrocardiograms should be ordered if patients are exposed to known cardiac toxins. MetHb levels should be checked when there is suspicion for oxidative stress on the red blood cells.

153.2 A 32-year-old woman presents following exposure to an irritant gas at her job site. She reports cough, burning eyes, and shortness of breath. She has mild tachypnea, with the remainder of her vital signs within normal limits. Her oxygen saturation is 96% on room air. She is noted to have stridor on physical examination. What is the preferred method to evaluate her upper airway symptoms?

A. Arterial blood gas (ABG)
B. Chest radiograph
C. Computed tomography of the neck
D. Fiberoptic laryngoscopy
E. Soft tissue neck radiograph

Answer: D. Fiberoptic or direct laryngoscopy is the preferred method to evaluate upper airway symptoms after exposures to irritant gases. Radiographs and laboratory tests have no role and should not influence the decision to provide a definitive airway. Symptoms can progress rapidly, so patients with upper airway symptoms require either placement of a definitive airway or close observation with frequent serial examinations.

153.3 A 52-year-old man is brought to the emergency department (ED) after being rescued from a house fire. He has not suffered any cutaneous burns. He complains of a sore throat, hoarse voice, and cough. Vital signs are normal. Physical examination reveals soot in his oropharynx and carbonaceous sputum. What therapy should be instituted first?

A. Endotracheal intubation
B. Intravenous (IV) methylprednisolone
C. Nebulized albuterol
D. Nebulized sodium bicarbonate
E. Saline bronchoalveolar lavage

Answer: A. Endotracheal intubation should be performed early in patients with signs and symptoms of significant airway burns (as this patient has). Corticosteroids are not beneficial and can worsen associated injuries. Inhaled beta-agonists are commonly used, but there is no evidence of improved outcome. Inhaled sodium bicarbonate plays no role in the management of smoke inhalation. Bronchoalveolar lavage can be performed if there is suspicion of inhaled debris or toxins, but the airway should first be secured.

153.4 A 47-year-old woman is brought to the emergency department (ED) after being rescued from a house fire. She was found unconscious at the scene and intubated before arrival. Her vital signs are significant for hypotension and tachycardia. Physical examination is significant for soot in the oropharynx. No cutaneous burns are noted. You suspect that she is suffering from cyanide poisoning. What is the most appropriate immediate therapy?

A. Hyperbaric oxygen (HBO)
B. Intravenous (IV) hydroxocobalamin
C. IV methylene blue
D. IV sodium nitrite
E. Observation and supportive care
Answer: B. One of the two major treatments for cyanide poisoning is hydroxocobalamin (the other is the cyanide antidote kit). The nitrite compounds in the cyanide antidote kit convert hemoglobin to methemoglobin (MetHb), which in turn binds to cyanide. However, nitrites produce hypotension and the MetHb prevents proper oxygen delivery, which may compound the reduction in oxygen delivery associated with carbon monoxide (CO) poisoning. HBO has no role in hydrogen sulfide poisoning. Sodium thiosulfate is necessary in treating methemoglobinemia. General supportive care is not appropriate because there is an antidote for this patient’s poisoning.

153.5. A 22-year-old man is brought to the emergency department (ED) after being found unconscious in a car with an intentionally prominent suicide note visible in the window. By the time he arrives in the ED, he has regained consciousness and is complaining of headache and nausea. Paramedics report that the car engine was not running when the patient was discovered. His vital signs and physical examination are normal. Which of the following therapies should be instituted?

- A. Hyperbaric oxygen (HBO)
- B. Intravenous (IV) methylene blue
- C. IV sodium nitrite
- D. IV sodium thiosulfate
- E. Observation and supportive care

Answer: E. This patient has been exposed to hydrogen sulfide (a common form of suicide in some parts of the world), which has similar effects on the mitochondria as cyanide. However, hydrogen sulfide is rapidly removed from the body; and as long as patients are recovering, removal from the source is usually all that is necessary. HBO and methylene blue have no role in hydrogen sulfide poisoning. Sodium nitrite can be used in patients who are not recovering once removed from the source or for severe exposures. Sodium thiosulfate is not necessary because hydrogen sulfide is detoxified by a different pathway than cyanide and does not need a sulfur donor.

153.6. A 51-year-old man is brought to the emergency department (ED) after being found unconscious and was intubated by emergency medical services (EMS) before arrival. His vital signs reveal hypotension but are otherwise normal. His physical examination is nonspecific. On 100% oxygen by endotracheal tube, his pulse oximetry reveals 100% saturation. Results of an arterial blood gas (ABG) are pH 7.05, partial pressure of carbon dioxide (Pco₂) 27 mm Hg, and partial pressure of oxygen (Po₂) 65 mm Hg. Which one of these findings is inconsistent with simple carbon monoxide (CO) poisoning?

- A. Hypotension
- B. Oxygen saturation 100%
- C. Pco₂ 27 mm Hg
- D. pH 7.05
- E. Po₂ 65 mm Hg

Answer: E. Measurement of oxygen saturation and Po₂ values is complicated in CO poisoning. Carboxyhemoglobin (COHb) is essentially falsely read as oxyhemoglobin by pulse oximeters, so a high oxygen saturation is expected by pulse oximetry. Po₂ is a measurement of dissolved oxygen in the blood; this result is independent of CO exposure and is not useful in determining whether CO poisoning is present; thus it should be normal. Metabolic acidosis with an elevated lactate is common because CO impairs aerobic metabolism; respiratory compensation is appropriate.

153.7. What is the major benefit of hyperbaric oxygen (HBO) therapy for patients suffering from carbon monoxide (CO) poisoning?

- A. Decreased rate of hospitalization
- B. Improvement of 24-hour mortality
- C. Improvement of 30-day mortality
- D. Prevention of delayed cardiovascular complications
- E. Prevention of delayed neuropsychiatric complications

Answer: E. There is controversy regarding the role of HBO therapy for patients with CO poisoning, but the best evidence suggests that it can significantly decrease the incidence of delayed neuropsychiatric complications. There is no change in rate of hospitalization, nor on overall mortality, either short term or long term. There are no delayed cardiovascular symptoms associated with CO poisoning.

153.8. Assuming that all patients have similar vital signs and complaints of headache and nausea, which of the following patients suffering from carbon monoxide (CO) poisoning should be considered highest priority for hyperbaric oxygen (HBO) therapy?

- A. A 22-year-old otherwise healthy man with a carboxyhemoglobin (COHb) level of 30%
- B. A 25-year-old otherwise healthy pregnant woman with a COHb level of 25%
- C. A 30-year-old otherwise healthy man also suffering from cyanide poisoning with a COHb level of 15%
- D. A 35-year-old otherwise healthy woman with second-degree burns to 20% of her body and with a COHb level of 20%
- E. A 67-year-old asymptomatic woman with coronary artery disease and with a COHb level of 25%

Answer: B. Pregnant patients should be considered for HBO therapy. CO binds more strongly to fetal hemoglobin than to adult hemoglobin and can cause severe hypoxia to the fetus. There is controversy about an absolute level of COHb that requires HBO therapy. HBO does not benefit cyanide victims, nor is it indicated in uncomplicated burn patients or those with stable comorbidities.
CHAPTER 154

Lithium

Jillian L. Theobald | Steven E. Aks

PRINCIPLES OF TOXICITY

Lithium has been used therapeutically since the mid-1800s where it was initially prescribed to treat gout. Lithium compounds such as lithium bromide were historically used as a hypnotic, whereas lithium chloride was introduced as a table salt alternative for heart failure patients in the twentieth century until its removal from the United States market. Lithium was approved for the treatment of bipolar disorder in 1970, and it remains one of the most effective agents for both depressive and manic symptoms.

Lithium is a monovalent cation with a narrow therapeutic range, and significant toxicity can result when outside of this range. Lithium largely has no effect when given in therapeutic doses to patients without mood disorders. In spite of long-term therapeutic use, the mechanism by which lithium acts is still not fully understood. Its efficacy in the treatment of psychiatric illnesses is thought to be due to the modulation of neurotransmitters, which has downstream effects through cell signaling and molecular mechanisms.\(^1\,^2\)

Lithium is rapidly absorbed from the gastrointestinal tract and peaks in the serum 1 to 2 hours after ingestion of immediate release preparation and 4 to 5 hours with sustained release preparations. In overdose situations, absorption and peak concentrations may be delayed. Once absorbed, lithium enters the serum followed by a delayed distribution to the tissues. In therapeutic dosing, lithium reaches a steady state within about 6 hours after the last dose. Therefore, lithium levels must be interpreted in the context of the dosing. Sustained-release formulations or concretions formed in the gut may extend the time to peak absorption well beyond 6 hours in the overdose setting. Lithium is not metabolized and is excreted unchanged in the urine. Any changes in renal excretion due to conditions such as dehydration, hyponeatremia, or renal dysfunction will lead to increases in serum lithium levels.

CLINICAL FEATURES

The classic presentation of significant lithium toxicity comprises altered mental status; tremors; hyperreflexia, clonus, or fasciculations; and vomiting or diarrhea. However, clinical features of lithium toxicity depend on whether it is acute or chronic in nature (Table 154.1). Thus, evaluation of the potentially lithium toxic patient requires knowledge of whether the patient was previously taking lithium, the timing of the last dose, and the amount of drug ingested. Acute toxicity usually follows a recent ingestion in a patient who is not therapeutically taking lithium. Acute toxicity typically manifests with gastrointestinal symptoms such as vomiting and diarrhea and can mimic many other disease states. Neurologic consequences of an acute lithium overdose (such as, altered mental status and seizures) occur several hours later after lithium redistributes to the brain, but in some cases where lithium has delayed-release properties, this can occur even 12 or more hours after ingestion. These consequences are similar to chronic lithium toxicity. Chronic toxicity is caused by an increase in serum levels of lithium in a patient who is regularly taking lithium. This can either be from reduced excretion, renal insufficiency, or dose adjustment (either by a clinician or by the patient). Chronic lithium toxicity causes predominantly neurological symptoms. Acute-on-chronic toxicity occurs when a patient with a stable steady-state lithium level takes a substantial additional amount of lithium, whether intentional or accidentally. These patients present with a combination of both acute and chronic toxicity signs and symptoms. Either acute or chronic toxicity can result in cardiac conduction abnormalities or bradycardia; however, these are uncommon.\(^3\)

Long-term chronic use of lithium can lead to nephrogenic diabetes insipidus and hypothyroidism. Both of these conditions are reversible with discontinuation of the medication and respond well to conventional management.\(^4\) Hypercalcemia and hyperparathyroidism also can occur and reverse upon discontinuation of lithium. Patients chronically taking lithium can develop the syndrome of irreversible lithium-effectuated neurotoxicity (SILENT). Patients with SILENT will often have persistent cerebellar and brain stem dysfunction, dementia, and extrapyramidal signs even after lithium use has been discontinued for more than 2 months. Use of lithium during early pregnancy may increase the risk for cardiovascular abnormalities in the fetus.\(^5\) Women taking lithium who present to the emergency department (ED) with newly diagnosed pregnancy should follow up with an obstetrician for fetal evaluation and monitoring.

DIFFERENTIAL DIAGNOSES

Lithium toxicity is nonspecific and may present in a manner similar to many systemic and neurologic disorders, so obtaining a history of use or ingestion is critical to making the diagnosis. Nausea and vomiting is common with viral syndromes and also with ingestion of many pharmaceuticals, such as salicylates and iron. The neurological manifestations of lithium toxicity (such as, tremors, seizures, and altered mental status) may prompt consideration of withdrawal syndromes, such as from alcohol or benzodiazepines, sympathomimetic toxicities (cocaine and amphetamines), serotonin syndrome, and neuroleptic malignant syndrome.

DIAGNOSTIC TESTING

Lithium concentrations should be obtained in all patients who are taking lithium, or have access to lithium, and present with potential toxicity. Because of the insidious and nonspecific nature of chronic lithium toxicity, a serum lithium level is also advisable in patients who are on lithium maintenance, regardless of their reason for presentation (Box 154.1). Therapeutic serum concentrations of lithium are between 0.6 mEq/L to 1.2 mEq/L. Serum levels are in a steady state about 6 hours after ingestion of a therapeutic dose; however, in overdose, peak concentrations can occur beyond 6 hours. We recommend obtaining serial
Lithium is highly dialyzable and dialysis is indicated for patients exhibiting signs of severe lithium toxicity (Box 154.2). Patients with severe neurological toxicity (such as, seizures, clonus, and hyperreflexia) should be dialyzed to reduce serum lithium levels below 1.0 mEq/L. Patients with impaired renal function or who cannot tolerate fluids will not be able to effectively eliminate lithium. In these patients, hemodialysis should be performed. The level of evidence for dialysis thresholds based solely on concentration is poor. We recommend, dialysis for serum levels above 4 mEq/L in acute toxicity and levels above 2.5 mEq/L in chronic toxicity regardless of symptoms. Serum lithium concentrations can rise or rebound after dialysis sessions, and a steady state concentration should be determined at 6 hours post-procedure.

**DISPOSITION**

Disposition depends largely on the extent of clinical toxicity and the psychiatric status of the patient. Patients manifesting clinical signs of neurotoxicity should be admitted. Patients with an acute overdose with significant cardiologic or neurologic symptoms and increasing lithium levels should be admitted to a hospital with hemodialysis capabilities. In these cases, we recommend consultation with a regional poison center or medical toxicologist. Patients with large ingestions of sustained release lithium should also be placed in observation status or hospitalized for serial monitoring of lithium concentrations until declining serum levels are documented. Patients with significant altered mental status, seizures, or requiring dialysis should be monitored in an intensive care or equivalent unit. Patients who are asymptomatic with normal physical examination findings 6 hours after ingestion of immediate release lithium preparations or 12 hours after a sustained release preparation can be discharged or cleared for psychiatric evaluation.

**BOX 154.2**

**Indications for Dialysis in Lithium Poisoned Patients**

- Severely symptomatic patients
- Unable to tolerate fluid hydration
- Renal impairment
- Acute toxicity: Levels above 4 mEq/L
- Chronic toxicity: Levels above 2.5 mEq/L

**BOX 154.1**

**Diagnostic Testing for Lithium**

- Serum lithium level
- Serum electrolytes
- Electrocardiogram (ECG)
- If the clinical picture dictates: Acetaminophen/salicylate levels, Thyroid function tests
The clinical pattern of acute and chronic toxicity is different. Gastrointestinal symptoms occur early and neurological toxicity manifest late in acute toxicity. Neurological findings (such as, tremors, clonus, and somnolence) often are presenting signs of chronic lithium toxicity and gastrointestinal symptoms may be absent.

Neither activated charcoal nor whole bowel irrigation (WBI) is indicated in the routine management of acute or chronic lithium toxicity.

Serial lithium concentrations should be obtained every 2 to 4 hours initially to determine the peak level and the need for dialysis.

Fluid hydration with crystalloid is essential to enhance the removal of lithium through the kidney. Diuretics are contraindicated.

We recommend dialysis for acute lithium concentrations >4 mEq/L, and chronic lithium concentrations >2.5 mEq/L, or for patients with signs of severe neurological toxicity regardless of the concentration.

CHAPTER 154: QUESTIONS & ANSWERS

154.1. What are the two most common electrolyte abnormalities seen in chronic lithium toxicity—hypernatremia and hypercalcemia?

A. Hyperkalemia
B. Hypernatremia
C. Hypokalemia
D. Hypomagnesemia
E. Hyponatremia and hypercalcemia

Answer: E. Hyponatremia and hypercalcemia are frequently seen in cases of acute lithium overdose. Chronic lithium use can cause hypernatremia.

154.2. Which of the following conditions is most frequently seen in patients with chronic lithium use?

A. Anticholinergic syndrome
B. Diabetes insipidus
C. Hyperthyroidism
D. Hypoparathyroidism
E. Syndrome of inappropriate antidiuretic hormone

Answer: B. Diabetes insipidus commonly occurs in patients on chronic lithium therapy or with chronic overdose. Diabetes insipidus can cause dehydration and a further increase in lithium concentration and is a frequent contributory cause to chronic lithium toxicity. Rarely, hypothyroidism can also develop. Lithium use is also associated with neuroleptic malignant syndrome and serotonin syndrome but none of the other listed conditions.

154.3. Which of the following drugs should be used with caution in patients taking lithium?

A. Acetaminophen
B. Hydrochlorothiazide
C. Metformin
D. Metoprolol
E. Penicillin

Answer: B. Hydrochlorothiazide, other diuretics, angiotensin-converting enzyme (ACE) inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs) can increase lithium levels and consequently cause chronic lithium toxicity by interfering with renal elimination. Lithium has also been implicated in serotonin syndrome when combined with other drugs, such as monoamine oxidase (MAO) inhibitors, selective serotonin reuptake inhibitor (SSRIs), dextromethorphan, and meperidine. None of the other drugs listed causes significant interactions with lithium.

154.4. A 26-year-old woman presents following a witnessed seizure. She was found with an empty bottle of lithium and a suicide note. Her vital signs reveal hypotension and tachycardia. She is lethargic, and her only response is to withdraw from painful stimuli. The remainder of her physical examination is normal. Laboratory tests including a serum lithium level are pending. Which of the following treatments is the most appropriate?

A. Activated charcoal
B. Forced diuresis
C. Hemodialysis
D. Urinary alkalinization
E. Whole bowel irrigation (WBI)

Answer: C. Hemodialysis is the most effective way to remove lithium. It can remove lithium at a rate five to seven times the rate of typical renal elimination. Common indications for dialysis include decreased level of consciousness and seizures. Activated charcoal does not adsorb lithium. Lithium overdose patients are often dehydrated and occasionally hyponatremic and should be fluid resuscitated, but once dehydration is corrected, forced diuresis is of no benefit and can be detrimental. Similarly, urinary alkalinization causes more harm than good and should be avoided. Because this patient has already experienced a seizure, the administration of WBI is not advised. In addition, the seizure suggests that the brain concentration of lithium is already toxic and this is not improved by WBI.
In general, low-potency FGAs are the most sedating, but also lead to the synthesis of chlorpromazine. It was discovered that patients treated with this drug became sedate and apathetic (neuroleptic effects), and chlorpromazine was first used successfully to treat a patient with psychosis in 1951. Antipsychotics were revolutionary because, prior to their development, pharmacotherapy for psychosis had focused on tranquilization rather than modification of disease.1,2

In 1956, clozapine was synthesized and demonstrated that a drug could treat psychosis without significant extrapyramidal effects at therapeutic doses. Agranulocytosis led to clozapine’s withdrawal from the market in 1974. It was reintroduced with mandatory monitoring in 1990 because of its efficacy in treatment-resistant schizophrenia. Clozapine became the precursor of the atypical antipsychotics.3,4

The term neuroleptic has since been replaced with antipsychotic, because newer agents are less sedating. Antipsychotic medications are used to treat schizophrenia, schizoaffective disorders, mania, anxiety disorders, and psychoses (including those associated with substance use and withdrawal). In the last decade, antipsychotic prescribing has increased dramatically, including off-label and non-psychotherapeutic use.5 In 2013, more than 45,000 exposures and 150 deaths attributable to antipsychotics were reported to the poison control centers in the United States. In addition to sedatives and hypnotics, antipsychotics comprised the group of drugs with the greatest increase per year in serious adverse outcomes.6

All antipsychotics are dopamine receptor antagonists. Multiple schemas exist for classification of antipsychotic medications, including chemical structure, clinical effects, receptor affinities, and adverse effects. Commonly, antipsychotics are divided into typical, or first-generation antipsychotics (FGAs), and atypical, or second-generation antipsychotics (SGAs). This division is based on the premise that SGAs exhibit less extrapyramidal symptoms, treat negative symptoms of thought disorders, and typically have 5-hydroxytryptamine type 2A (5-HT₂A) serotonin receptor antagonism in addition to dopamine receptor antagonism. FGAs are sometimes also classified as low-potency or high-potency on the basis of their affinity for the dopamine D₂ receptor subtype (Box 155.1).7 In general, low-potency FGAs are the most sedating. Movement disorders are significant adverse side effects of FGAs. Movement disorders also occur with SGAs but with lower frequency. Although neuroleptic malignant syndrome (NMS) can occur with all antipsychotic agents, it occurs with much less frequency with SGAs.8

Pathophysiology

Antipsychotic medications have both psychiatric and non-psychiatric clinical uses, and they are widely used and widely available. The antiemetic effects of prochlorperazine, promethazine, and droperidol are secondary to blockade of dopamine receptors in the chemoreceptor trigger zone of the medulla. Prochlorperazine and droperidol abort migraine headaches by preventing dopamine-mediated meningeal artery vasodilation. Chlorpromazine is the historical drug of choice for intractable hiccups, although other antipsychotics have since been used.9,10 Haloperidol and pimozide are FDA-approved treatments for Tourette syndrome, although several SGAs have also been used experimentally.11

Toxicity of antipsychotic drugs can be broadly divided into three categories: exaggeration of pharmacologic effects (as occurs in acute overdose), undesired clinical effects occurring in therapeutic use such as extrapyramidal syndromes, and idiosyncratic effects such as NMS.

Most antipsychotics exert effects at other receptors and ion channels in addition to D₂ receptor antagonism. Common “off-target” effects include alpha-1 adrenergic receptor antagonism, muscarinic acetylcholine receptor antagonism, histamine H₁ receptor antagonism, fast voltage-gated sodium channel blockade, and delayed potassium rectifier channel blockade.

Alpha antagonism may result in orthostatic hypotension. Muscarinic antagonism can produce minor side effects in therapeutic use or frank anticholinergic toxicity in acute overdose. Many FGAs have other properties similar to antihistamines including sedation, both in therapeutic use and overdose.

Phenothiazine antipsychotics, including mesoridazine and thioridazine, are structurally related to tricyclic antidepressants (TCAs) and similarly exhibit sodium channel blockade that may lead to wide complex dysrhythmias. Many agents inhibit potassium rectifying currents resulting in QT prolongation and, potentially, torsades de pointes. The degree of prolongation varies between antipsychotics, increasing in a dose-dependent manner, and with concomitant use of other QT-prolonging drugs.12 A direct correlation between degree of QT prolongation and risk of torsades de pointes has not been established, but antipsychotics are associated with increased risk of sudden death, particularly with comorbid cardiac disease and in elderly patients.13,14 Psychotic disorders alone are also associated with increased risk of sudden death.15 Clozapine can lead to myocarditis sometimes accompanied by eosinophilia and eosinophilic myocardial infiltrates in which a type I hypersensitivity mechanism has been proposed.16

Antipsychotic drugs distribute throughout the brain and block dopamine receptors in multiple regions. Mesolimbic D₂ blockade is desirable in reducing positive symptoms of schizophrenia. However, at similar degrees of D₂ receptor occupancy, blockade of D₂ receptors in the nigrostriatal pathway produces undesired extrapyramidal symptoms. Extrapyramidal symptoms can be immediate or delayed after initiation of drug therapy. Acute extrapyramidal symptoms include dystonia, akathisia, and drug-induced Parkinsonism. Second generation antipsychotics, in general, have lower affinity for the dopamine receptor and have serotonin receptor antagonism, both of which are believed to reduce extrapyramidal symptoms.17,18 The propensity for antipsychotics to produce extrapyramidal symptoms is inversely proportional to the agent’s muscarinic receptor antagonism.18
Rapid dissociation from the D₂ receptor is also hypothesized to reduce the risk of extrapyramidal symptoms, as in the case of clozapine.¹⁹

Tardive dyskinesia and tardive dystonia may develop after prolonged use of dopamine blocking medications and have been reported with all antipsychotics. One proposed pathophysiologic mechanism for tardive dyskinesia is chronic dopamine receptor blockade in the nigrostriatal pathway leading to D₂ receptor upregulation and hypersensitivity to dopamine.²⁰

The pathophysiologic mechanism of NMS, an idiosyncratic reaction to antipsychotic medication, is poorly understood. It is hypothesized that D₂ receptor blockade in the nigrostriatal pathway leading to D₂ receptor upregulation and hypersensitivity to dopamine.²¹

The historical incidence of agranulocytosis in patients treated with clozapine was approximately 1%. With mandated white blood cell count monitoring, the incidence in the United States dropped to 0.38%.²² Although the mechanism of agranulocytosis is unclear, research supports an immunogenic cause and direct cytotoxic effect on human bone marrow mesenchymal stromal cells.²²

Therapeutic use of antipsychotics has been associated with weight gain, dyslipidemia, glucose intolerance, new-onset diabetes, and the metabolic syndrome.²³

Antipsychotic drugs have been associated with an increased risk of venous thromboembolic (VTE) disease, primarily in observational and case-control studies. Multiple hypotheses have been proposed to explain the association, including metabolic effects and the possibility that thought disorders may predispose patients to VTE disease.²⁴ The risk of VTE disease may be highest with clozapine, olanzapine, and low-potency FGAs.²⁴

### Acute Overdose

In overdose, antipsychotics produce signs and symptoms that are exaggerations of their pharmacologic profile. Most patients develop symptoms within a few hours post-ingestion. Paliperidone has a unique delayed-delivery system and late onset of symptoms has been reported.²⁵ Central nervous system (CNS) depression is common, ranging from mild sedation to coma. Anticholinergic delirium and agitation may result from drugs with antimuscarinic effects (Box 155.2). Airway reflexes can be impaired and respiratory depression can occur after overdose. Pupils may be of variable size; anticholinergic effects promote mydriasis, whereas miosis, resulting from alpha-antagonism, may mimic opioid toxicity. Mild orthostatic hypotension is also a common finding from alpha-adrenergic blockade.²⁶

Variable evidence suggests that antipsychotics lower seizure threshold; however, with the exception of clozapine, seizures rarely occur in overdose. Acute extrapyramidal symptoms have also been reported in overdose.²⁶,²⁷

### Acute Extrapyramidal Syndromes

_Acute dystonia_ presents with involuntary spasms of antagonistic muscle groups most often involving facial, neck, back, or limb muscles. This results in trismus, facial grimacing, dysarthria, tongue and lip distortion, torticollis, or oculogyric crisis. Half of patients who develop acute dystonia do so within 48 hours of receiving the implicated drug. Symptoms may develop rapidly or may be delayed hours to days, although most acute dystonias develop within 5 days of drug administration. Recurrent dystonic reactions may occur, even following a single dose of an antipsychotic.²⁸ __Laryngeal dystonia__, a rare but life-threatening form of dystonia, manifests as dyspnea, stridor, choking sensation, or respiratory distress and has been reported with both FGAs and SGAs.²⁹ Increased risk of death due to choking has been reported in patients treated for schizophrenia; a review of sudden deaths in schizophrenia patients listed airway obstruction as cause of death in 7.8%.³⁰,³¹

_Akathisia_ (from Greek, _“unable to sit”_) is characterized by subjective feelings of internal restlessness associated with objective motor findings, including repetitive foot shuffling, truncal shifting, or pacing. Akathisia usually develops within hours to days of initiating or increasing the dose of an antipsychotic. One study reported that almost half of emergency department (ED) patients given 10 mg of intravenous (IV) prochlorperazine...
developed akathisia within 1 hour. However, subsequent studies of ED patients have demonstrated markedly decreased incidence, ranging from 5% to 15%, with slower drug infusion.3–33

Drug-induced Parkinsonism manifest by bradykinesia, mask-like facies, shuffling gait, rigidity, and tremor may occur in up to 60% of patients treated with antipsychotics and frequently develops 2 to 4 weeks after initiating treatment. Ninety percent of cases develop within 3 months.28

Rabbit syndrome is a perioral, tongue-sparing dyskinesia in which rhythmic lip and nose movements resemble the chewing movements of a rabbit. Rabbit syndrome is also associated with prolonged antipsychotic therapy.35

Tardive Dyskinesia

Tardive dyskinesia is a chronic and sometimes permanently disabling movement disorder induced by prolonged use of dopamine antagonists, including antipsychotic medications. Typical signs of tardive dyskinesia include rapid, involuntary movements of the face (chewing, blinking, grimaces, and tongue movements). Tardive dyskinesia may also cause abnormal limb, truncal, or pelvic movements. The risk of tardive dyskinesia with sustained antipsychotic treatment is estimated around 5% per year and may be higher in the elderly. Prevalence is estimated at approximately 20% of psychiatric patients undergoing long-term treatment. Tardive dyskinesia is difficult to treat and is frequently permanent, with age and duration of treatment associated with irreversibility.36 Reduction of the antipsychotic dose or a change to an alternative agent should be considered. Amantadine, levetiracetam, and clonazepam have improved symptoms in clinical trials.35

Respiratory dyskinesia is a variant of tardive dyskinesia that is characterized by orofacial dyskinesia, dyspnea, dysphonia, and respiratory alkalosis. This chronic disorder often goes undiagnosed and can cause repeated bouts of aspiration pneumonia.36

Neuroleptic Malignant Syndrome

NMS is a serious idiosyncratic drug reaction that is potentially life threatening. NMS typically develops during the first 2 weeks of therapy but has occurred during long-term drug regimens. The incidence of NMS in developed countries has been reported as approximately 2% of patients exposed to antipsychotics.33,34 Risk factors include rapid dose escalation, cumulative drug dosage, high-potency antipsychotics, parenteral formulations, dehydration, preceding psychomotor agitation, prior brain injury, poorly controlled extrapyramidal symptoms, and previous episodes of NMS. Concomitant treatment with lithium increases the risk for NMS.34,36–40 Abrupt withdrawal from dopaminergic agents used to treat Parkinson’s disease may cause a syndrome clinically indistinguishable from NMS, termed Parkinsonian-hyperpyrexia syndrome or neuroleptic malignant-like syndrome.36 All antipsychotic agents have been implicated in NMS, including SGAs.36

NMS is characterized by altered mental status, muscular rigidity, hyperthermia, and autonomic instability (Table 155.1). Other features of NMS may include sialorrhea, dysarthria, dysphagia, metabolic acidosis, elevated transaminases, sodium imbalance, dehydration, elevations in catecholamines, generalized slowing on electroencephalogram (EEG), coagulopathy, pulmonary embolism, and renal failure.34,36

Most patients have the cardinal features of altered mental status, muscle rigidity, hyperthermia, and autonomic instability within 1 to 2 weeks after starting an antipsychotic or abruptly increasing the dose.44 However, the signs of NMS may develop gradually and in any order. Clinicians should discontinue antipsychotic drugs in patients with suspected NMS. Most episodes resolve with appropriate care within 2 weeks after cessation of the offending medication; symptoms may wax and wane for months.45

Cardiovascular Toxicity

The most common cardiac effect is sinus tachycardia with a normal QRS duration. A few FGAs can cause QRS prolongation; however, co-ingestions should be considered. QT prolongation should be considered a “class effect” of all antipsychotic medications. QT prolongation occurs during therapeutic dosing and in overdose of many antipsychotic agents. Therapeutic doses of thioridazine, followed by ziprasidone, prolong the QT interval more than risperidone, olanzapine, quetiapine, or haloperidol.44 QT prolongation associated with torsade de pointes is a well-described adverse effect of thioridazine, mesoridazine, droperidol, haloperidol, chlorpromazine, sertindole, sulpiride, and pimozide.44,46 Among SGAs, ziprasidone carries the greatest risk of QTc prolongation. SGAs, ziprasidone carries the greatest risk of QTc prolongation, and torsades de pointes has been reported with amisulpride overdose.47–49

Myocarditis has been reported in less than 1% of patients taking clozapine. The majority of cases develop in the first 2 months of treatment. A nonspecific, flu-like prodrome frequently precedes the onset of myocarditis by days to weeks. The spectrum of disease ranges from subclinical, asymptomatic disease to decompensated heart failure.50

Agranulocytosis

Clozapine can produce life-threatening agranulocytosis; most cases develop within 6 weeks to 6 months of starting the drug. With monitoring and treatment, attributable mortality is approximately 1 in 10,000.5 Agranulocytosis has not been reported after acute clozapine overdose. Among other antipsychotics, the risk of

Seizures

The incidence of new-onset seizures among patients treated with antipsychotics is higher than the background rate in the general population, suggesting antipsychotic medications can lower the seizure threshold. Phenothiazines have been shown in observational studies to increase the risk of seizures. However, antipsychotic-related seizures are rare in therapeutic use except for clozapine, which causes a dose-related increase in risk of seizures (up to 5% at high doses) and induces electroencephalographic abnormalities. Antipsychotics can be prescribed for patients with a known seizure disorder.

Differential Diagnoses

The differential diagnosis of antipsychotic toxicity includes a broad list of agents and clinical conditions that produce altered mental status, orthostatic hypotension, anticholinergic toxidrome, seizure, QT prolongation, or torsades de pointes, such as TCAs. The differential diagnosis of NMS includes malignant catatonia, serotonin syndrome, heatstroke, sympathomimetic toxicity, acute salicylate poisoning, and other medical conditions (Table 155.2). Malignant hyperthermia should also be considered in patients receiving inhalational anesthetics or succinylcholine.

Diagnostic Testing

Quantitative blood levels of antipsychotics are neither readily available nor helpful. As with any patient who presents with suspected drug toxicity, blood glucose concentration, serum acetaminophen level, and directed toxicologic screening are recommended. Aspiration is common among patients with depressed mentation; chest radiography should be performed in hypoxic patients.

An electrocardiogram (ECG) should be obtained in all patients with suspected overdose and in those taking antipsychotics therapeutically with symptoms concerning for cardiotoxicity. If QT prolongation is present, serum potassium, calcium, and magnesium levels should be measured.

Patients who have NMS, extrapyramidal symptoms with marked muscle rigidity, or prolonged seizures are at risk for rhabdomyolysis. In such patients we recommend serum creatinine kinase, assessment of renal function, and urine myoglobin measurements.

Patients who are severely hyperthermic (>40° C) are at risk for multi-system organ failure and disseminated intravascular coagulation. Because severe salicylate poisoning can cause CNS toxicity and hyperthermia due to uncoupling of oxidative phosphorylation, we recommend a serum salicylate level, in addition to serum transaminases and coagulation studies.

Patients taking clozapine, chlorpromazine, or olanzapine who present with infection or fever should be evaluated for neutropenia. We also recommend testing white blood cell counts in patients on other antipsychotics who present with unusual infections or fever without source.

Atypical antipsychotics have been associated with new-onset diabetes and diabetic ketoacidosis (DKA). This typically occurs soon after the onset of treatment and sometimes in the absence of weight gain. Patients in whom DKA is clinically suspected should have blood pH measurement and serum or urine ketones. Salicylism can also produce a clinical picture that mimics DKA.

Other tests, such as brain computed tomography, lumbar puncture, and drug screens may be helpful in some cases to exclude other diagnoses or establish a comorbid condition, but are not indicated when the context and presentation support uncomplicated antipsychotic toxicity as the cause.

Management

General

Treatment of antipsychotic overdose is supportive. Endotracheal intubation and mechanical ventilation may be required due to CNS depression or to support respiration. Dextrose should be given to patients with hypoglycemia. Neither gastric emptying nor activated charcoal is indicated for antipsychotic toxicity. See Chapter 139 for a discussion of the roles of activated charcoal and other methods of gastric decontamination.

If sedation and miosis suggest opioid intoxication, a trial of naloxone is warranted. We recommend administering naloxone 0.4 to 2.0 mg intravenous push (IVP) every 2 to 3 minutes and, if effective, titrating to return of normal respiratory rate, oxygenation, and ventilation.

Anticholinergic Toxicidrome

Physostigmine has been used to treat anticholinergic (antimuscarinic) delirium from antipsychotic overdoses. Contraindications to physostigmine include reactive airway disease and cardiovascular disease (including any intraventricular conduction delay, bradycardia, or heart block). Physostigmine will usually cause a decrease in heart rate through enhanced vagal tone. We recommend avoiding its use in patients who present with seizures, because physostigmine may precipitate additional seizures. In adult patients who have obvious central anticholinergic delirium with agitation, we use physostigmine 1 to 2 mg IV, infused over 5 minutes in the absence of contraindications. In patients in whom agitated delirium is present but the toxidrome is unclear, we use lorazepam 1 to 2 mg IV every 10 to 15 minutes titrated to mild sedation. The delirium reversal effect of physostigmine is usually short-lived (45 to 60 minutes). The use of physostigmine for reversal of anticholinergic delirium does not preclude the use of benzodiazepines for sedation and vice versa.

Seizures

Antipsychotic-induced seizures may be short, self-terminating, and not require pharmacologic treatment. For multiple seizures or status epilepticus, first line treatment is lorazepam 0.1 mg/kg (maximum 4 mg) given intravenously at a rate of 2 mg/min. This dose may be repeated in 5 minutes if seizures have not terminated. Refractory seizures unresponsive to lorazepam can be treated with phenobarbital (15 to 18 mg/kg IV loading dose). In patients who do not have a response to high doses of benzodiazepines (especially patients who are intubated), propofol may be administered (0.3 to 1.25 mg/kg of body weight, up to 4 mg/kg per hour). Use of propofol in this way generally requires intubation and initiation of continuous EEG monitoring if available.

Acute Extrapyramidal Syndromes

Dystonia will usually respond within 30 minutes to dophyhydr-damine 25 to 50 mg or benztrapine 1 to 2 mg intravenously, intramuscularly, or orally. Lorazepam 1 to 2 mg IV may also be effective in patients who do not respond within 1 hour to diphenhydramine or benztrapine. IV lorazepam may be repeated in 15 to 20 minutes if dystonia is not improved. Akathisia is treated
mild and resolving or ECG intervals have normalized. Sinus tachycardia with normal ECG intervals is expected in overdose and need not be treated unless secondary cardiac injury is present. Widening of the QRS due to sodium channel blockade is uncommon and is managed similarly to cyclic antidepressant toxicity. We recommend sodium bicarbonate 1 to 2 mEq/kg IVP, which may be repeated every 3 to 5 minutes until QRS narrowing (<114 msec) occurs. Boluses may be repeated or an infusion of 150 mEq/L of sodium bicarbonate in 5% dextrose in water may be infused at twice calculated maintenance rate and titrated to a goal blood pH of 7.5 to 7.55.

**Cardiotoxicity**

Cardiac monitoring is recommended in patients who are symptomatic or those with ECG abnormalities until the symptoms are similarly. Patients with akathisia who fail to respond to the above treatments can be given propranolol 10 mg by mouth twice daily until symptoms improve, although supporting evidence is limited. Treatment of drug-induced Parkinsonism includes minimizing the effective antipsychotic dose. Acute therapy begins with an anticholinergic agent, dosed as for dystonia.

*Other clinical entities to consider in the differential diagnosis of NMS include: CNS infection, status epilepticus (including nonconvulsive status), alcohol or sedative hypnotic withdrawal, hypocalcemia, hypoglycemia, hyponatremia, intracranial hemorrhage, other poisoning (eg, anticholinergics, nicotine, salicylates, strychnine, theophylline), sepsis, tetanus, thalamic infarct, thyroid storm, and psychogenic agitation. CNS, Central nervous system; ECT, electroconvulsive therapy; IV, intravenous; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.
Hypotension is generally mild and typically responds to IV sodium chloride bolus and infusion. We prefer sodium chloride as the crystalloid in these cases, because the sodium ion may be beneficial in the context of sodium channel blockade. If hypotension is severe, or persists after 2 L of isotonic crystalloid, a direct-acting vasopressor with alpha-adrenergic agonist is initiated. We recommend norepinephrine IV infusion, started at 1–2 mcg/min and titrated to maintain mean arterial pressure greater than 65 mm Hg.

Correction of hypokalemia, hypomagnesemia, and hypocalcemia shortens the QT interval. Adults with QTc greater than 500 msec or transient torsade de pointes should be given 2 to 4 g of magnesium sulfate IV. Treatment of sustained torsades de pointes includes IV magnesium sulfate up to 4 g total, defibrillation, overdrive pacing, or isoproterenol (see Chapter 69). Any drugs that prolong the QT interval should be avoided.

ED treatment of clozapine-induced myocarditis is supportive. Clozapine treatment should be stopped immediately when the diagnosis is suspected.

Neuroleptic Malignant Syndrome

Treatment of NMS consists of supportive care and discontinuation of all dopamine-blocking medications. Agitation, psychomotor hyperactivity, and muscle rigidity should be treated with liberal doses of IV benzodiazepines. Lorazepam is administered as 1 to 2 mg IV every 5 to 10 minutes, until muscle rigidity improves. Refractory cases or patients at risk for aspiration can be managed with intubation and neuromuscular blockade with a nondepolarizing agent (eg, rocuronium). Hyperthermia should be managed with IV fluids and evaporative cooling. To facilitate evaporative cooling, the patient’s bare skin is continually misted with water while a cooling fan blows air continuously across the skin surface. The goal of cooling is a reduction in core temperature to less than 39°C within 30 minutes. If rhabdomyolysis is present, it is treated as described in Chapter 119.

Bromocriptine, levodopa, amantadine, rotigotine, lisuride (available in EU, UK, and Canada), and apomorphine have all been tried for treatment of NMS but evidence of benefit is limited. Bromocriptine is a dopamine agonist and increases serotonergic transmission, so it risks exacerbating underlying psychiatric illness or serotonin syndrome. Dantrolene has also been successfully used for treatment of severe rigidity. As rigidity in NMS is believed to originate in the CNS rather than in myocytes, dantrolene offers no mechanistic advantage over benzodiazepines and nondepolarizing neuromuscular blockade. We do not recommend any of these agents as part of routine treatment of NMS.

Electroconvulsive therapy (ECT) may be used in cases of NMS refractory to pharmacologic treatment. Evidence for efficacy is limited, although it is proposed as a treatment of choice in malignant catatonia, which may be indistinguishable from NMS. We recommend ECT in cases of NMS that fail to demonstrate any improvement within 48 hours of benzodiazepine treatment and supportive therapies described earlier.

VTE disease is a prominent cause of morbidity and mortality in NMS. Patients with NMS should receive pharmacologic VTE prophylaxis.

**DISPOSITION**

Patients with NMS and overdose patients with hypotension, coma, torsades de pointes, or airway compromise should be admitted to an intensive care unit. Patients with a prolonged QT interval of any magnitude should have at least 12 hours of cardiac monitoring to ensure that the interval prolongation is resolving and QTc is less than 500 msec. Patients with minimal signs of toxicity should be observed for at least 6 hours from the time of ingestion, with hospitalization for persistent or worsening signs and symptoms. Criteria for hospital discharge include return to normal mental status and resolution of any vital sign, metabolic, and electrocardiographic abnormalities. Psychiatric consultation may be necessary to assess the risk of suicide. Patients with acute dystonia resolved by diphenhydramine or benztropine should continue the drug for 48 hours to prevent recurrence. Patients with drug-induced Parkinsonism who must continue antipsychotic medications may need to use anticholinergic agents long-term. Such patients should be discharged with diphenhydramine 25 to 50 mg by mouth every 6 hours or benztropine 1 to 2 mg by mouth twice daily for at least 48 hours and should be referred to their treating physician, who may reduce the antipsychotic dose or change treatment regimens as necessary. Benztropine, diphenhydramine, and some antipsychotic medications cause anticholinergic effects, so combination therapy may worsen dry mouth, blurred vision, and urinary retention.
REFERENCES

CHAPTER 155: QUESTIONS & ANSWERS

155.1. A 24-year-old man presents with cough and fever. He has schizophrenia for which he takes haloperidol. You diagnose him with community-acquired pneumonia. Which of the following antibiotics could cause a life-threatening arrhythmia if administered to this patient?
A. Amoxicillin/clavulanic acid
B. Azithromycin
C. Cefpodoxime
D. Clindamycin
E. Doxycycline

Answer: B. Antipsychotics can cause QT prolongation, so other drugs that cause QT prolongation should be avoided. Macrolides, fluoroquinolones, and trimethoprim-sulfamethoxazole are common antibiotics that can all cause QT prolongation.

155.2. A 42-year-old man presents complaining that his neck is turned to the right. He states he cannot move his head and his neck hurts. He denies trauma and states that this has never happened before. He has schizophrenia but does not recall the names of his medications. His vital signs are normal and examination reveals palpable spasm of the right trapezius and sternocleidomastoid muscles. What is the most appropriate treatment?
A. Bromocriptine
B. Cyclobenzaprine
C. Diphenhydramine
D. Morphine
E. Prochlorperazine

Answer: C. This patient has an acute dystonic reaction to an antipsychotic medication best treated with an anticholinergic medication, such as diphenhydramine or benztropine. Bromocriptine is a dopamine agonist used to treat pituitary disorders and can worsen psychosis. Cyclobenzaprine can be used for typical muscle spasms but will not significantly improve acute dystonia. Morphine may help but does not resolve the underlying problem. Prochlorperazine is an antipsychotic that can induce acute dystonic reactions and should be avoided in this patient.

155.3. A 22-year-old man is brought to the emergency department (ED) by family because of a change in mental status. They report that 2 days ago the patient had his psychiatric medications adjusted and has been confused since then. The patient's vital signs are: blood pressure, 162/100 mm Hg; heart rate, 143 beats/min; respiratory rate, 22 breaths per minute; and temperature, 40.1°C. On physical examination, the patient is found to have muscle rigidity. Laboratory tests are pending. Intravenous (IV) access is obtained, and crystalloid fluids are started. Cool mist and fans are applied to the patient. What additional therapy is indicated?
A. Acetaminophen
B. Cyproheptadine
C. Dantrolene
D. Diphenhydramine
E. Lorazepam

Answer: E. Lorazepam or another benzodiazepine is indicated in neuroleptic malignant syndrome (NMS). Acetaminophen plays no role in treating the hyperthermia, which should be treated with active cooling measures. Cyproheptadine can be used in serotonin syndrome but does not improve NMS. Dantrolene can be used in malignant hyperthermia but does not improve NMS. Diphenhydramine is used for acute dystonia and does not affect the course of NMS.

**Opioids**

Jenna K. Nikolaides | Trevonne M. Thompson

---

**PRINCIPLES OF TOXICITY**

*Opiate* is the term for natural agents derived from the poppy plant that have morphine-like pharmacological effects. Example opiates include morphine and codeine. *Opioid* is the more inclusive term, which refers to any synthetic, semisynthetic, or natural agent that has morphine-like properties. Some common semisynthetic opioids are heroin, hydrocodone, oxycodone, hydromorphone, oxymorphone, and buprenorphine. Some common synthetic opioids are fentanyl, methadone, and meperidine. Both *opiate* and *opioid* are terms derived from *opium*, which was the Greek word for the juice of the poppy plant (*Papaver somniferum*).1

Opioids are among the world’s oldest known drugs. The therapeutic use of opioids has been a practice since ancient times, with the primary goals being sedation and analgesia. Opioids act on receptors in the central nervous, cardiovascular, pulmonary, and gastrointestinal systems and can also be used therapeutically for their antitussive and antidiarrheal effects.

Pain is a common reason why patients present to the emergency department (ED). As much as 78% of ED visits are related to a painful condition.2 Since the Joint Commission placed increased attention on pain management and hospitals increased their emphasis on patient satisfaction, there has been a proliferation in the amount of opioid prescriptions written by physicians, including emergency providers.3 This trend has not led to an actual improvement in overall patient satisfaction but has led to a flood of available opioids into the wider population.4 According to the Centers for Disease Control and Prevention (CDC), there has been a 300% increase in the sale of opioid analgesics from 1999 to 2011. In 2010 alone, enough prescription opioids were prescribed to medicate every American adult with 5 mg of hydrocodone every 4 hours for 1 month.5 Consequently, the United States has seen a widespread rise in prescription opioid abuse, overdoses, and deaths. In 2010, approximately 12 million Americans, or 1 in 20, reported use of opioids without a prescription. Nearly 15,000 Americans die annually due to prescription opioid overdose, and overdoses overtook motor vehicle accidents as the number 1 cause of accidental death in 2010.6,7

There has been a concomitant resurgence in illicit heroin use. According to the CDC, the death rate from heroin overdose doubled across 28 states in just 2 years, between 2010 and 2012.7 There has also been a change in demographics of heroin use. Formerly involving primarily inner-city minority populations, the practice has spread geographically beyond urban areas and to white men and women in their late 20s.8 It is now believed that prescription analgesics are the gateway to heroin use, because the street price of heroin is often the cheaper option for opioid dependent patients.

The wider availability of opioids has affected every population group. This has been especially concerning for pediatric patients, because analgesic prescriptions written for adults can end up in the hands of children.9,10 Recreational opioid use may be associated with the teenage and young adult population, but unintentional opioid overdose is also a growing concern among chronic pain patients, geriatric patients, and obese patients; because risk is increased by polypharmacy, medical comorbidities, and sleep apnea.

Opioids come in three forms: synthetic, semisynthetic, and natural opiates. There are prescription versions of all three forms, which are available in many different preparations, including tablets, liquids, patches, and even lollipops. Prescription opioids are commonly packaged as combination preparations with acetaminophen, ibuprofen, and aspirin and historically existed in combinations with atropine and camphor. Other prescription oral preparations are formulated with opioid-receptor antagonists, such as naloxone, which has little oral bioavailability to prevent illicit use and tampering for intravenous abuse. There are also prescription drugs that are not chemically classified as opioids, but which display µ opioid receptor agonist, such as tramadol and tapentadol.

Illicit opioids also exist in all three forms. Table 156.1 details some of the known street names for opioids sold illicitly.11,12 Street names are often unreliable, however, because they are subject to dealers who may want to market or rebrand their product. Heroin (diacetylmorphine), a semisynthetic opioid, is the most widespread street preparation, but recent years have seen a rise in synthetics, such as fentanyl and fentanyl analogues, often mixed with or mislabeled as heroin.13 Illicit opioid preparations can also be contaminated by the byproducts from the manufacturing process, adulterated with additives to change the preparation’s pharmacological effects, and diluted with inert substances to increase bulk. The most common added substances are sugars, caffeine, over-the-counter medications, other drugs of abuse, heavy metals, and infectious agents.14-17

Toxicity can occur as a consequence of intentional overdose, intentional recreational abuse, or as an adverse effect of therapeutic use. Although different opioids have receptor preferences in therapeutic doses, this specificity is lost at higher doses. Opioids are well absorbed via gastrointestinal, intravenous, intramuscular, mucocutaneous, and subcutaneous routes of administration. Depending on the lipid solubility of the specific opioid, they can also be absorbed through nasal, buccal, pulmonary, or transdermal routes. In general, toxicity is less pronounced but more prolonged when ingested than with parenteral administration. In therapeutic doses, an ingested opioid is absorbed in the small intestine within 1 to 2 hours. In toxic doses, delayed gastric emptying prolongs the absorption and clinical effects of the opioid.

Most opioids have a large volume of distribution. Different opioids and their metabolites cross into the blood-brain barrier due to variations in lipid solubility. All opioids undergo hepatic metabolism and renal elimination. Thus changes in hepatic or renal function will alter drug clearance, which could prolong clinical and toxic effects of the specific opioid.

**CLINICAL FEATURES**

The hallmarks of the opioid toxidrome are central nervous system (CNS) depression, respiratory depression, and miosis. Miosis is caused by stimulation of µ receptors in the Edinger-Westphal
nuclei of the third cranial nerve. This effect may be unreliable or masked by co-ingestants, and thus respiratory depression is the essential feature of opioid intoxication. Respiratory depression is caused by opioids’ effect on the medullary respiratory center via suppressing its sensitivity to hypercapnia and overriding the hypoxic drive. When combined with CNS depression, prolonged hypopnea can lead to hypoxia causing further neurologic complications. Long-term opioid use is known to cause dependence and may be complicated by co-intoxicants. The essential finding in these findings is not consistently present, and the clinical picture may be complicated by co-intoxicants. The essential finding in opioid intoxication is respiratory depression. Other intoxica- tions may present similarly, such as clonidine, guanfacine, valproic acid, gamma-hydroxybutyrate, ethanol, sedative hypnotics, and atypical antipsychotics. Non-toxicologic considerations include pontine stroke or hemorrhage.

**DIFFERENTIAL DIAGNOSES**

The diagnosis of opioid intoxication is usually based on history, vital signs, and physical examination with recognition of its characteristic toxidrome: hypopnea, stupor, and miosis. All of these findings are not consistently present, and the clinical picture may be complicated by co-intoxicants. The essential finding in opioid intoxication is respiratory depression. Other intoxications may present similarly, such as clonidine, guanfacine, valproic acid, gamma-hydroxybutyrate, ethanol, sedative hypnotics, and atypical antipsychotics. Non-toxicologic considerations include pontine stroke or hemorrhage.

DIAGNOSTIC TESTING

No laboratory test or drug screen should be relied upon by a clinician to make the diagnosis of opioid toxicity. The presence of the toxidrome and rapid response to naloxone are the two most important diagnostic clues. End-tidal carbon dioxide and oxygen saturation monitoring may be helpful for recognition of respiratory depression and hypoxia, but are not as necessary as observation of the patient’s respiratory rate.

A 12-lead electrocardiogram is a useful diagnostic for identifying QRS widening, as seen in propoxyphene use, or for QTc prolongation, as seen in methadone use. If the patient has audible pulmonary rales on examination, then a chest radiograph is useful to evaluate for acute lung injury. If the opioid preparation is unknown, then acetaminophen and salicylate levels should be measured, because many prescription opioids are sold as combination preparations. Hypoglycemia is the only consistent laboratory abnormality found in opioid toxicity. It is generally mild but can contribute to the decreased level of consciousness seen in opioid overdose.

Opioids, such as morphine, codeine, and heroin, are reliably detected on most qualitative antibody-based enzymatic immunoassay urine toxicology screens. Some semisynthetic and synthetic opioids, such as hydrocodone, methadone, and fentanyl, however, are often missed on typical urine drug screens unless they are specifically measured. A urine test result can remain positive for up to 72 hours after last use, depending on the half-life of the drug used. A large poppy seed ingestion can lead to a positive opioid screen, although federal workplace testing guidelines have raised the confirmatory morphine concentration threshold to 2000 ng/mL to avoid positive screens for commonplace poppy seed ingestions.28,29 Advanced screening methods detecting for 6-monoacetylmorphine, a specific metabolite of heroin, can be used to confirm heroin use.19

MANAGEMENT

Stabilization and Supportive Care

The ED physician should direct efforts at stabilizing the patient’s airway, oxygenation, and ventilation. This can be accomplished with a combination of basic supportive measures and titrated use of antidotal therapy. Patients with acute lung injury may require oxygen and positive-pressure modalities, such as bi-level positive airway pressure, continuous positive airway pressure, or mechanical ventilation with positive end-expiratory pressure.

Decontamination

Because many opioids are extended-release preparations and also delay gastric motility, activated charcoal has been used in the past, but there are no data to support the effectiveness of this practice. Additionally, naloxone is an effective antidote for opioid overdose, and sedation from opioid intoxication could lead to charcoal aspiration. Gastric lavage similarly is not recommended because the risks outweigh the benefits. Whole bowel irrigation is not generally useful, but it can be considered for body packers (see Chapter 149).

Enhanced Elimination

There are no clinically effective techniques for enhanced elimination of opioids.

Antidote Therapy

Naloxone is a competitive opioid antagonist that rapidly reverses the effects of opioid intoxication. Because of the rapid clinical response, it can also aid in the diagnosis of opioid overdose. Naloxone is ineffective orally because its bioavailability is minimal due to first-pass metabolism. It is effective via intravenous, subcutaneous, intramuscular, inhalational, and endotracheal routes. It is indicated when an opioid intoxicated patient has significant CNS or respiratory depression.

In the ED, naloxone is usually administered intravenously with empirical dosing. The dose ranges from 0.04 mg to 15 mg, depending on the amount and formulation of the opioid taken, the patient’s weight, and whether the patient is opioid dependent. In general, it is best to start with low doses and to increase doses as needed to alleviate respiratory depression. The exception to this is the arrest or near-arrest situation where opioids are the suspected cause. In this scenario, recommended starting doses are 0.4–2.0 mg. In chronic opioid users, the minimal effective naloxone dose should be used so as not to precipitate acute withdrawal.

In this population, when respiratory status is adequate, we recommend starting with doses of 0.04 mg of naloxone, followed by titration of subsequent doses. Acute opioid withdrawal is unpleasant for the patient. Opioid withdrawal is not, in isolation, life-threatening, and naloxone has an excellent safety profile. The clinician should not be reluctant to dose naloxone as needed, even if opioid withdrawal symptoms develop.

Naloxone’s onset of action, when administered intravenously, is less than 2 minutes, and the duration of action is anywhere between 20 minutes and 2 hours, which is shorter than the duration of action of most opioids. Reversal of respiratory depression usually occurs at low doses, but dosing is repeated until the desired effect is achieved. If respiratory depression is not reversed after the administration of high doses of naloxone (10 to 15 mg), then it is unlikely that opioid intoxication is the cause of the symptoms. If naloxone does reverse the symptoms but the patient later develops recurrent respiratory depression, then repeated naloxone doses, a continuous naloxone infusion, or endotracheal intubation should be considered. When starting a naloxone infusion, one-half to two-thirds of the bolus dose that effectively reversed intoxication is given hourly, although individual patient responses may vary depending on dose, tolerance, and dependency. This is usually enough to maintain respiratory effort without producing withdrawal.

In situations where intravenous access is not easily obtained, naloxone can also be given via intramuscular, intranasal, or nebulized routes. Intranasal naloxone has proved a viable, alternative to intravenous administration, especially for prehospital providers. Both 0.4 mg/mL and 1 mg/mL solutions of naloxone, delivered into each nare using an atomizer device, have been used.30 Nebulized naloxone—2 mg of naloxone is mixed with 3 mL of saline—has also been shown to be a safe, effective, and gradual way to reverse opioid intoxication in both the ED and prehospital settings.32,33 Care must be taken in selecting the optimal patient for nebulized naloxone. A patient with profound respiratory depression, such as a respiratory rate of less than six breaths per minute or cyanosis, will not receive enough naloxone to obtain the desired clinical effect.

Nalmefene and naltrexone are opioid antagonists with longer half-lives and duration than naloxone. Nalmefene’s duration of action is 4 to 10 hours, and naltrexone’s duration of action is 24 to 72 hours. These are generally not used in the ED because of concern for inducing a prolonged withdrawal state. Naloxone titration remains the treatment of choice for opioid reversal in the acutely intoxicated patient.

DISPOSITION

Patients who present with heroin toxicity can be successfully treated in the ED. Opioid-toxic patients who use longer acting opioids may require an observation admission. Body stuffers who remain asymptomatic after 6 hours of observation may be
Withdrawal occurs in tolerant patients when opioids are stopped or an antagonist is administered. In withdrawal, the patient goes into a hyperadrenergic state. The symptoms include yawning, piloerection, CNS excitation, tachypnea, mydriasis, tachycardia, hypertension, nausea, vomiting, diarrhea, abdominal cramps, and myalgias. CNS excitation takes the form of restlessness, agitation, dysphoria, and insomnia. Cognition and mental status are usually unaffected. In general, opioid withdrawal is uncomfortable but not life-threatening. As with opioid toxicity, no diagnostic test exists for opioid withdrawal. It is diagnosed based on the patient’s symptoms and signs.

Treatment for the withdrawing patient in the ED is supportive and symptom-based: intravenous fluids, electrolyte replacement, and antiemetics. Clonidine, an alpha2-agonist, can be used to suppress sympathetic hyperactivity and shorten the duration of withdrawal. For long-term maintenance therapy, addiction clinics can provide or prescribe methadone, a long-acting opioid, as a replacement for heroin to both prevent withdrawal and treat addiction. Buprenorphine and buprenorphine-naloxone combined as a single product have recently been added to the outpatient treatment armamentarium for opioid abuse. Opioid withdrawal alone typically does not require inpatient treatment. Some patients with severe symptoms may require admission.

CHAPTER 156: Questions & Answers

156.1. Most opioids cause mild hypotension related to histamine release and bradycardia. Which of the following opioids can also cause sodium channel blockade and QRS widening? A. Hydromorphone B. Meperidine C. Morphine D. Oxycodeone E. Propoxyphene

Answer: E. Propoxyphene and its metabolite norpropoxyphene can cause QRS widening. None of the other listed opioids has significant effects on the cardiac conduction system.

156.2. Which of the following laboratory abnormalities is most commonly seen in opioid overdose? A. Hyponatremia B. Hypochloremia C. Hypoglycemia D. Hypokalemia E. Hypoproteinemia

Answer: C. Hypoglycemia is the only consistent laboratory abnormality found to contribute to the decreased level of consciousness seen in opioid overdose.

156.3. A 32-year-old man presents with confusion, nausea, vomiting, diarrhea, and abdominal pain. His friends report that he is withdrawing from heroin. Vital signs reveal mild hypertension, tachycardia, and tachypnea. Physical examination is significant for confusion, mydriasis, diaphoresis, lacrimation, piloerection, and mild diffuse abdominal tenderness. Which of the following signs and symptoms makes you concerned that this may not be a simple opioid withdrawal case? A. Confusion B. Diarrhea C. Mydriasis D. Piloerection E. Tachycardia

Answer: A. Opioid withdrawal almost always causes restlessless, agitation, and anxiety. Cognition and mental status are not affected in simple opioid withdrawal and, if present, should prompt the clinician to search for other causes instead of or in addition to withdrawal.

156.4. A 20-year-old woman is brought to the emergency department (ED) after being found with decreased mental status at a club. Vital signs indicate mild hypotension and bradycardia. She is drowsy but...
1946.e2

PART IV Environment and Toxicology | SECTION TWO Toxicology

arousable, and she has an otherwise normal physical examination. Upon receiving naloxone 2 mg IV, her mental status immediately improves and soon thereafter she vomits. She now reports nausea but has no other complaints. She states she took some “pain pills” to get high but does not know what they were. What diagnostics tests should be performed?

A. Acetaminophen
B. Arterial blood gas
C. Chest radiograph
D. Lactate
E. Urine drug screen

**Answer:** A. Because many prescription opioid medications are combinations of an opioid and acetaminophen, ibuprofen, or salicylate, concentrations of acetaminophen and salicylate should also be ordered. Acetaminophen overdose might otherwise remain undiagnosed but, if identified, can be treated with an existing antidote, N-acetylcysteine. The chest radiograph is not indicated unless a pulmonary complication is suspected. Lactate and a urine drug screen would not change patient management.

156.5. Which of the following medications can be used to treat opioid withdrawal?

A. Clonidine
B. Dextromethorphan
C. Diphenhydramine
D. Nalmefene
E. Valproic acid

**Answer:** A. Clonidine suppresses the sympathetic hyperactivity of opioid withdrawal. Dextromethorphan is an opioid derivative used as a cough suppressant, but it does not treat the symptoms of opioid withdrawal. Diphenhydramine and valproic acid have no role in opioid withdrawal. Nalmefene is an opioid antagonist similar to naloxone but with a longer duration of action. Administration of nalmefene would worsen opioid withdrawal symptoms.

156.6. A 14-month-old child is brought to the emergency department (ED) 4 hours after he was found with his grandmother’s antidiarrheal medication bottle. A pill count identifies that only one Lomotil tablet is missing. The child is playful, has a normal respiratory rate and pattern, and has a soft abdomen with normal bowel sounds. Appropriate management includes which of the following?

A. Administration of activated charcoal
B. Administration of naloxone
C. Admission to a monitored unit
D. Discharge home
E. Gastric lavage

**Answer:** C. Activated charcoal and gastric lavage are means of gastrointestinal decontamination and are not routinely recommended in opioid toxicity. Opioid intoxicated patients with central nervous system (CNS) and respiratory depression should be treated with naloxone, but asymptomatic patients do not require antidote administration. Asymptomatic patients with known or suspected Lomotil (diphenoxylate/atropine) ingestion should be observed in a monitored setting for delayed onset of toxicity from the metabolite of diphenoxylate.

156.7. An 18-year-old male is driven to the emergency department (ED) by friends and carried into the triage area. He has agonal respirations and is cyanotic. Immediate resuscitative measures include bag-valve-mask (BVM) ventilation, establishment of an intravenous (IV) line, and administration of 0.4 mg of naloxone. The patient’s respiratory status improves and although sleepy, he is able to answer some questions. During subsequent monitoring, the patient’s respiratory status again declines, and he requires two additional doses of naloxone. Additional treatment should include which of the following?

A. Nalmefene
B. Naloxone infusion
C. Hemodialysis
D. Suboxone
E. Subutex

**Answer:** B. This patient likely has toxicity from a long-acting opioid agent, and a continuous infusion of naloxone will be necessary for ongoing reversal of toxicity. Nalmefene is a longer-acting opioid antagonist but is not preferred over naloxone infusion because naloxone allows for dose titration. Suboxone and Subutex are agonist agents used in the treatment of withdrawal. Opioids are not dialyzable due to large volumes of distribution.

156.8. A 26-year-old female is brought to the emergency department (ED) from the local airport by law enforcement. She is sleepy and mumbles incoherently in a foreign language. Vital signs include the following: blood pressure, 104/66; respiratory rate, 14 breaths per minute; and temperature, 98.6° F. Which of the following tests might identify the cause of this patient’s symptoms?

A. Abdominal radiograph
B. Electrocardiogram (ECG)
C. Electroencephalogram (EEG)
D. Head computed tomography (CT)
E. Urine drug screen

**Answer:** A. An abdominal radiograph would likely reveal multiple packets of illicit opioid in the gastrointestinal tract of this body packer. One or more of the packets has leaked, producing the opioid toxicity. A urine drug screen may not identify an opioid but would not identify the internal packets. A head computed tomography (CT) scan would not be helpful unless associated head trauma is suspected. An EEG and ECG would not provide specific information to identify the internal packets.
Pesticide is a general term that refers to all pest-killing agents, and so it includes insecticides, herbicides, rodenticides, and fungicides. In this chapter, several classes of pesticides will be discussed, as well as their importance in the emergency department (ED) setting (Table 157.1).

ORGANOPHOSPHATE INSECTICIDES

Principles of Toxicity

Organophosphates are a class of insecticide pesticides that work by inhibiting cholinesterases, including acetylcholinesterase and pseudocholinesterase. This is both the mechanism of their efficacy as insecticides as well as their toxicity in humans. Inhibition of cholinesterases result in accumulation of acetylcholine at multiple receptors within the autonomic nervous system, the sympathetic and parasympathetic ganglionic nicotinic sites, postganglionic cholinergic sympathetic and parasympathetic muscarinic sites, skeletal muscle nicotinic sites, and central nervous system sites (Fig. 157.1).

Organophosphates are lipid soluble and are absorbed through dermal, gastrointestinal, and respiratory routes. This can lead to deposition in fat tissues allowing for possible toxicity from acute and chronic, low-level exposures. Some organophosphates have active metabolites that can result in delayed toxicity.

Clinical Features

Organophosphate toxicity is represented by the “SLUDGE” or “DUMBELS” syndrome (these are mnemonics, which are explained in Box 157.1) manifested by accumulation of acetylcholine at receptor sites. The clinical features in any given case are attributable to the location of the receptors affected, the properties of the specific organophosphate product (predominance of nicotinic versus muscarinic effects), and the dose of the exposure. Muscarinic acetylcholine accumulation leads to salivation, lacrimation, urinary incontinence, defecation, emesis, bronchospasm, bronchorrhea, and bradycardia. Nicotinic acetylcholine accumulation leads to tachycardia, tachydysrhythmias, and skeletal muscle fasciculations.

At the neuromuscular junction, excess acetylcholine causes hyperstimulation of the muscles with secondary paralysis, and when the diaphragm is affected, cholinesterase poisoning leads to respiratory arrest. Sympathetic stimulation can lead to diaphoresis. A combination of sympathetic stimulation, involvement of the N-methyl-D-aspartate (NMDA) receptor, and enhanced acetylcholine concentrations can induce seizures.

Pulmonary edema can occur in organophosphate poisoning and should not be confused with bronchorrhea or bronchospasm. Pulmonary edema results from many factors, including the release of inflammatory mediators and cells and increased vascular permeability. Bronchospasm and bronchorrhea are mediated by both central and local mechanisms involving acetylcholine. Pulmonary edema, bronchospasm, bronchorrhea, and the aforementioned respiratory muscle paralysis all contribute to respiratory failure.

Although the classic clinical picture of acute organophosphate poisoning is obvious, toxicity from gradual, cumulative exposure may be subtle. These patients commonly exhibit vague confusion or other central nervous system complaints; mild visual disturbances; or chronic abdominal cramping, nausea, and diarrhea.

A unique feature of organophosphate insecticides is the process called aging, the irreversible conformational change that occurs when the organophosphate is bound to the cholinesterase enzyme for a prolonged time. This causes the clinical effects to persist for periods of days to weeks. The time to aging varies by the specific product involved. Once an enzyme has aged, an oxime antidote (discussed later) cannot regenerate the cholinesterase.

Differential Diagnoses

The differential diagnosis for acetylcholinesterase inhibitor poisoning is limited. Carbamate pesticides, carbamate medications (such as, rivastigmine), nicotine and other nicotine alkaloids, and cholinomimetics (such as, pilocarpine) are xenobiotics that can cause a similar constellation of symptoms. There are few medical conditions included in the differential diagnosis: conditions causing exaggerated vagal response (such as, inferior wall myocardial infarction) and conditions that cause exaggerated sympathetic responses (such as, thyroid storm or pheochromocytoma).

Diagnostic Testing

Patients who present with the classic toxidrome should be treated empirically without waiting for laboratory confirmation of decreased cholinesterase activity. Known or suspected exposures to organophosphates can be evaluated by assessing plasma and erythrocyte (red blood cell [RBC]) cholinesterase concentrations. These concentrations are not generally available in real-time clinical settings.

In acute toxicity, plasma cholinesterase levels decrease first. In chronic, low-level exposure, however, plasma enzyme levels may be normal but RBC cholinesterase may still be decreased. This is because plasma cholinesterases can recover in 4 to 6 weeks, whereas RBC cholinesterases can take as long as 12 weeks to recover. Other laboratory studies should focus on the evaluation of pulmonary, cardiovascular, and renal function and fluid and electrolyte balance. A measurement of acid-base status should be performed, because patients with acidosis have higher mortality than those without. Other prognostic tools such as the Glasgow Coma Scale or the Poison Severity Score vary by type of organophosphate and are generally of little utility.

Management

Treatment of organophosphate poisoning is directed toward four goals: (1) decontamination, (2) supportive care with an emphasis on respiratory stabilization, (3) reversal of acetylcholine excess, and (4) reversal of oxime binding at receptor sites on the cholinesterase molecule. The severity of the patient’s signs and symptoms guides management.

Decontamination

Decontamination begins in the out-of-hospital phase to prevent further absorption and subsequent toxicity and to protect care providers. Because dermal absorption is likely, removal and destruction of clothing and thorough flushing of exposed skin limits absorption and toxicity. Alternatively, dermal decontamination can be done with dry agents, such as military resins, flour, sand, or bentonite. Due to availability and ease of flushing, however, this is the method of decontamination we recommend, unless water is not available. Caregivers are at risk for contamination from splashes or handling of contaminated clothing. Personnel may be rotated to limit their exposure to encounters with either multiple contaminated patients or patients extensively contaminated (or contaminated with a high concentration product). Caregivers should use universal precautions, including eye shields, protective clothing, and nitrile or butyl rubber gloves. In the case of ingestion, neither gastrointestinal decontamination procedures nor activated charcoal are of benefit. Anticholinergic agents are rapidly absorbed and profuse vomiting and diarrhea are seen early in ingestion, negating any beneficial effect of additional gastrointestinal decontamination. Equipment, but not skin, may be washed with a 5% hypochlorite solution.

Stabilization and Supportive Care

Because death is a result of airway and respiratory failure, supportive care should be directed primarily toward airway management and include suctioning of secretions and vomitus, oxygenation, and, when necessary, ventilatory support. Succinylcholine, 1.5 mg/kg, is commonly used as a paralytic drug for emergency orotracheal intubation. Succinylcholine is metabolized by cholinesterases and may have a prolonged duration of effect (4 to 6 hours) in the setting of organophosphate poisoning. If succinylcholine is used as a paralytic drug, anticipate the need for prolonged sedation and ventilatory support. A nondepolarizing paralytic drug not metabolized by cholinesterases (such as, rocuronium, 1 mg/kg) is preferable. Tachycardia and tachydysrhythmia generally resolves by treating the underlying cholinergic excess and should not be treated symptomatically (eg, with beta blockers). Patients with agitation, seizures, and coma should be treated with...
adequate doses of a benzodiazepine after the airway has been secured.

Enhanced Elimination
There is no role for enhanced elimination or hemodialysis in organophosphate poisoning.

Antidote Therapy
Definitive treatment for organophosphate poisoning is aimed at decreasing the amount and effect of acetylcholine at its various receptor sites. This begins with atropine. Atropine is a competitive inhibitor of acetylcholine at muscarinic receptors. The atropine dose for the treatment of organophosphate poisoning is 1 to 3 mg (0.05 mg/kg in children) intravenously with doubling of each subsequent dose every 5 minutes until there is control of the muscarinic effects, particularly reduction in airway secretions. Atropine may be initiated intramuscularly until intravenous or intraosseous access is obtained. Depending on the specific organophosphate product involved and the degree of poisoning, patients may require 200 to 500 mg of atropine during the first hour. Once the patient has been stabilized with appropriate “atropinization,” an infusion is initiated to provide 10% to 20% of the total cumulative dose needed to obtain symptom control per hour. Tachycardia and mydriasis may occur at these atropine doses but are not an indication to stop therapy; however, excessive administration of atropine may cause the typical symptoms of the anticholinergic toxidrome. The endpoint of atropinization is drying of respiratory secretions, easing of respiratory effort, and normalization of respiratory rate. Early and rapid atropinization is associated with better control of seizures and reduced mortality in animal models. The recommended atropine dosing regimen can easily exhaust available hospital supplies, and arrangements for this situation should be discussed with the appropriate hospital personnel early in the case of an organophosphate poisoning. Other anticholinergic medications, such as diphenhydramine and anticholinergic ophthalmic drugs, have been studied in rodents, and may be considered a “last resort” alternative in humans if anticholinergic ophthalmic drugs, have been studied in rodents, or if patients early in the case of an organophosphate poisoning. Antidote therapy is aimed at countering the muscarinic effects, such as respiratory muscle paralysis. The second part of the treatment of organophosphate poisoning is the use of an oxime to regenerate acetylcholinesterase function. Oximes bind to the organophosphate-cholinesterase complex causing a conformational change that allows for the cholinesterase to resume normal function. There are currently five oximes in common use worldwide: pralidoxime (2-PAM), trimedoxime (TMB-4), obidoxime chloride (Toxogonin), methoxime, and asoxime chloride (HI-6). Pralidoxime is the product commonly available in the United States. There are controversies regarding the use of oximes related to dosing, duration of treatment, time to therapy initiation, and effectiveness in treating neurologic symptoms. Despite these controversies, we recommend oximes for the treatment of moderate or severely poisoned patients, defined as those who require multiple, large doses of atropine. Indications for oxime treatment include respiratory depression or failure, muscle fasciculations, seizures, dysrhythmias, hemodynamic instability, or the use of large amounts or repeated doses of atropine to completely control signs and symptoms of organophosphate intoxication. We recommend administering pralidoxime as a 1 to 2 g bolus (25 to 50 mg/kg in pediatric patients) over 30 minutes, which can be repeated as needed (up to hourly) based on response (improved mental status, respiratory and heart rate, and decreased secretions). Even higher doses may be required. Alternative dosing options are: 2 g bolus over 20 minutes followed by an infusion of 500 mg/h for up to 7 days, 1 g/h every 4 hours, or 30 mg/kg followed by infusion of 8 mg/kg per hour (Table 157.2). OXimes can be given intravenously or intramuscularly (as evidenced by autoinjectors).

Novel treatments for organophosphate and nerve agent poisoning are under investigation. At present, pyridostigmine is the most commonly used prophylactic drug; other prophylactics include tablets containing pyridostigmine, trihexyphenidyl and benactyzine, as well as a transdermal patch containing H-series oximes (HI-6).

Disposition
Most patients who present to the ED after significant organophosphate exposure should be admitted to a monitored setting. The effects of organophosphate intoxication can be prolonged. If plasma cholinesterase levels are available, they may be useful for treatment and disposition decisions. Asymptomatic or minimally symptomatic patients with normal or minimally depressed cholinesterase levels may be discharged after 6 hours with close outpatient follow-up to ensure that progressive toxicity does not occur. Patients who present with significant symptoms (acute respiratory compromise associated with depressed cholinesterase levels) require admission and close monitoring, usually in an intensive care unit (ICU). Patients may have rebound toxicity several days after apparently satisfactory response to initial treatment. This may occur for many reasons, including persistent release of organophosphates from lipid stores. Poisoning with fenthion is of particular concern, because initial symptoms could be mild and progress to life-threatening intoxication over time. Those patients with acts of self-harm or suicidal intent require psychiatric consultation once medically stabilized.

The intermediate syndrome (IMS) can occur after the acute intoxication from organophosphates has resolved. IMS is delayed muscle paralysis, including respiratory muscles, which can occur 24 to 96 hours after the resolution of the cholinergic crisis. The precise cause of IMS is not well documented. Finally, delayed peripheral neuropathy may occur 7 to 21 days after acute organophosphate intoxication. Therefore, close patient follow-up is important after stabilization.

Carbamate Insecticides
Carbamates are acetylcholinesterase inhibitors whose toxicological picture is similar to organophosphates. There are two

Chlorinated Hydrocarbons Insecticides

Dichlordiphenyltrichloroethane (DDT) is the best-known example of chlorinated hydrocarbon insecticides. This class is also known as organochlorine insecticides. DDT was developed in the late 1800s and first used widely in World War II to prevent transmission of typhus and malaria. It was found to be effective and stable and led to the development of other similar insecticides that were used agriculturally, industrially, and residually. Their widespread and indiscriminate use, long half-life, and persistence in the environment resulted in ecologic effects that lead to a ban on most chlorinated hydrocarbons. In the United States, gamma-hexachlorocyclohexane (also known as lindane) is a chlorinated hydrocarbon insecticide available as pharmaceutical drug for the second-line treatment of head lice and scabies. The state of California has banned lindane, and the state of Michigan has restricted its use to physician’s offices only.8,11

Principles of Toxicity

Chlorinated hydrocarbon insecticides are highly lipid soluble. They are readily absorbed via dermal, respiratory, and gastrointestinal routes and are stored in fatty tissues. This storage allows for toxicity from repeated, low-level exposure. Lindane toxicity often occurs from excessive external (dermal) exposure or accidental oral exposure.

Chlorinated hydrocarbon insecticides affect neuronal voltage-gated sodium channels. They are also gamma-aminobutyric acid (GABA) antagonists. This results in hyperexcitability and irritability of both central and peripheral neurons. Chlorinated hydrocarbons also increase susceptibility to ventricular tachydysrhythmias because of increased myocardial sensitivity to circulating catecholamines.

Clinical Features

The primary clinical feature of chlorinated hydrocarbon insecticide toxicity is neurologic excitation. This includes muscle fasciculations, ataxia, tremors, delirium, weakness, paralysis, paresthesias, seizures, and death.11 Mild premonitory symptoms are not always present prior to serious neurological manifestations that patients can present only with seizure activity. Hyperthermia can result from muscle fasciculations and seizures. Metabolic acidosis, respiratory failure, and acute renal failure can also occur. Chronic exposure can cause liver toxicity, arrhythmias, menstrual changes, and neuropsychological effects. The most important clue to diagnosing exposure to chlorinated hydrocarbons is a detailed history because there is no specific toxidrome.

Differential Diagnoses

The defining features of chlorinated hydrocarbon insecticide toxicity are neuro-excitation and seizure. The differential diagnosis is broad and includes any disorder or toxic exposure that can lead to seizures (eg, organophosphates, isoniazid, theophylline, sympathomimetic agents, lead, ethanol, and benzodiazepine withdrawal).

Diagnostic Testing

The diagnosis of chlorinated hydrocarbon insecticide poisoning is determined by history and clinical features. Some reference laboratories can measure chlorinated hydrocarbons from fat or plasma samples, but this will not be readily available during emergency treatment. An electrolyte panel, creatinine kinase, and blood gas are to be measured on patients with known or suspected acute poisoning.

Management

Decontamination

The first step in chlorinated hydrocarbon insecticide toxicity is decontamination. Remove all clothing and wash the skin and hair with soap and water. Ingested chlorinated hydrocarbons are rapidly absorbed by the gastrointestinal tract; therefore, decontamination with activated charcoal is of no use.

Stabilization and Supportive Care

The main objective in treating chlorinated hydrocarbon toxicity is cessation of seizures. Benzodiazepines and barbiturates are the mainstays of therapy to treat seizures. Chlorinated hydrocarbons can cause myocardial sensitization that can lead to ventricular tachydysrhythmias, which are most commonly seen around the time of seizure activity due to a catecholamine surge. Beta-adrenergic antagonists (such as, intravenous metoprolol, 5 mg boluses every 5 minutes) are recommended for treating any life-threatening tachydysrhythmias (such as, ventricular tachycardia and fibrillation) in this situation. Prolonged seizures can lead to hyperthermia. Seizure control with benzodiazepines and external cooling with evaporative cooling methods should be implemented if hyperthermia is present. Other complications such as metabolic acidosis, rhabdomyolysis, and acute kidney injury are treated with intravenous hydration and, in the case of rhabdomyolysis, alkalinization, as described in Chapter 119.

Enhanced Elimination

There is no role for enhanced elimination of chlorinated hydrocarbon insecticides in the ED.

Antidote Therapy

There is no antidotal therapy for chlorinated hydrocarbon insecticides.

Disposition

Patients who present symptomatic with chlorinated hydrocarbon insecticide poisoning require admission for evaluation, monitoring, and treatment of neurologic and metabolic derangements.

**SUBSTITUTED PHENOLS**

**Principles of Toxicity**

Dinitrophenol (DNP), pentachlorophenol, and dinitrocresol belong to a class of compounds called substituted phenols and have been used as dyes, wood preservatives, photograph developers,
and insecticides. DNP was previously used as a weight loss medication but has not been available by prescription since 1938 because of fatalities associated with its use. DNP is currently used as a weight loss supplement and is readily available over the Internet. It can be easily obtained from online nutritional supplement retailers and is available in powder, capsule, and crystalline form. The most common route of exposure is oral, but substituted phenols can also be absorbed dermally and can be inhaled.

Substituted phenols uncouple oxidative phosphorylation. This results in decreased adenosine triphosphate (ATP) formation and increased heat generation, which is the mechanism of action for DNP in weight loss because calories are burned excessively. DNP also stimulates glycolysis, which, along with the uncoupling of oxidative phosphorylation, increases lactic acid production.

Clinical Features

Patients with acute toxicity from substituted phenols present with hyperthermia, tachycardia, diaphoresis, and tachypnea. Neurologic signs and symptoms include confusion, agitation, seizures, and coma. Rhabdomyolysis, myocardial injury, acute kidney injury, and hepatic damage can occur in acute toxicity. These patients can progress to cardiovascular collapse and death. Dermal exposure can cause a yellow discoloration and corrosive injury.

Differential Diagnoses

Patients suffering from the toxic effects of substituted phenols will appear to have sympathomimetic excess. This leads to a broad differential diagnosis that includes toxicologic, infectious, and environmental considerations, such as cocaine toxicity, encephalitis, and heat stroke (Table 157.3; see Chapter 149). An accurate history is important to the diagnosis of substituted phenol intoxication.

Diagnostic Testing

Diagnostic testing focuses on the metabolic disturbances and potential organ damage associated with acute substituted phenol toxicity. Serum electrolytes and renal function are to be assessed. Liver studies should be performed, and creatinine kinase is measured to assess for rhabdomyolysis. An electrocardiogram (ECG) and laboratory assessment for myocardial injury with serial cardiac markers (troponin) is advised for any patient with symptoms consistent with myocardial ischemia.

Management

Decontamination

Patients who present with dermal exposure should have the clothing removed and skin washed with soapy water. Because of the potential lethality of phenol-containing compounds with no effective antidote, a patient who presents within 1 hour of an acute oral ingestion and who is alert and cooperative should be given oral activated charcoal (at least 100 g in adults).

Stabilization and Supportive Care

Supportive care is the mainstay of treatment for substituted phenol toxicity. Patients with hyperthermia (temperature >102.5°F) should be cooled with evaporative cooling, cooling blanket, cold intravenous fluids, ice packs, and whatever other methods available. All patients should be given adequate fluid resuscitation, and electrolyte derangements should be corrected. This is especially important in hyperthermic patients. Agitation and seizures treated with benzodiazepines, such as lorazepam (1 to 2 mg intravenous push [IVP]) or diazepam (5 to 10 mg IVP).

Enhanced Elimination

There is no known role for enhanced elimination in substituted phenol toxicity.

Antidote Therapy

There is no antidote for acute phenol poisoning.

Disposition

Patients who manifest symptoms after substituted phenol exposure should be admitted for intensive cardiac and neurologic monitoring and treatment. A patient who presents asymptomatic after an exposure is observed for 8 to 12 hours and may be safely discharged if they remain asymptomatic over that period of time.

CHLOROPHENOXY HERBICIDES

Principles of Toxicity

Chlorophenoxy compounds are effective herbicides for broad-leaved weeds. This class of herbicides includes 2-methyl-4-chlorophenoxyacetic acid (MCPA), methylchlorophenoxypropionic acid (MCPP), and 2,4-dichlorophenoxyacetic acid (2,4-D). Chlorophenoxy herbicides are widely used in both commercial and residential settings.

Chlorophenoxy herbicides are absorbed through the gastrointestinal tract, skin, and respiratory tract. Most cases of toxicity, however, result from ingestion. Skeletal muscle is the primary organ of toxicity, although the exact mechanism of action is not well defined. Proposed mechanisms of action include direct cell membrane damage, forming analogues of acetyl-CoA and acting as false cholinergic messengers, and at high doses, uncoupling oxidative phosphorylation.

Clinical Features

Ingestion of chlorophenoxy herbicides can result in gastrointestinal symptoms that include vomiting, abdominal pain, diarrhea, oropharyngeal burning, and gastrointestinal hemorrhage. Other symptoms include muscle fasciculations, weakness, myotonia, and decreased tendon reflexes. Myotonia and fasciculations may lead to rhabdomyolysis and metabolic acidosis.

Differential Diagnoses

Severe toxicity from chlorophenoxy herbicides is rare. When symptoms are present, other possible diagnoses include other

- **Caffeine**: Used as a weight loss supplement and is readily available over the Internet. It can be easily obtained from online nutritional supplement retailers and is available in powder, capsule, and crystalline form. The most common route of exposure is oral, but substituted phenols can also be absorbed dermally and can be inhaled.

- **DNP (Dinitrophenol)**: Previously used as a weight loss medication but has not been available since 1938 due to fatalities associated with its use. DNP is currently used as a weight loss supplement and is readily available over the Internet. It can be easily obtained from online nutritional supplement retailers and is available in powder, capsule, and crystalline form. The most common route of exposure is oral, but substituted phenols can also be absorbed dermally and can be inhaled.

- **Clinical Features**: Patients with acute toxicity from substituted phenols present with hyperthermia, tachycardia, diaphoresis, and tachypnea. Neurologic signs and symptoms include confusion, agitation, seizures, and coma. Rhabdomyolysis, myocardial injury, acute kidney injury, and hepatic damage can occur in acute toxicity. These patients can progress to cardiovascular collapse and death. Dermal exposure can cause a yellow discoloration and corrosive injury.

- **Differential Diagnoses**: Patients suffering from the toxic effects of substituted phenols will appear to have sympathomimetic excess. This leads to a broad differential diagnosis that includes toxicologic, infectious, and environmental considerations, such as cocaine toxicity, encephalitis, and heat stroke (Table 157.3; see Chapter 149). An accurate history is important to the diagnosis of substituted phenol intoxication.

- **Diagnostic Testing**: Diagnostic testing focuses on the metabolic disturbances and potential organ damage associated with acute substituted phenol toxicity. Serum electrolytes and renal function are to be assessed. Liver studies should be performed, and creatinine kinase is measured to assess for rhabdomyolysis. An electrocardiogram (ECG) and laboratory assessment for myocardial injury with serial cardiac markers (troponin) is advised for any patient with symptoms consistent with myocardial ischemia.

- **Management**: Decontamination

Patients who present with dermal exposure should have the clothing removed and skin washed with soapy water. Because of the potential lethality of phenol-containing compounds with no effective antidote, a patient who presents within 1 hour of an acute oral ingestion and who is alert and cooperative should be given oral activated charcoal (at least 100 g in adults).
causes of acute myopathy. When gastrointestinal symptoms are present, ingestion of caustic substances, organophosphate, and carbamate exposure are other considerations.

**Diagnostic Testing**

Testing for chlorophenoxy herbicides is not available in the emergency setting. Diagnostic testing should focus on assessing skeletal muscle damage and its consequences. Measurement of creatine kinase, electrolyte profile, renal function, liver function, and acid base status are indicated.

**Management**

**Decontamination**

In the case of a dermal exposure, remove the clothing and wash the skin with soapy water. Because chlorophenoxy herbicides are rapidly absorbed via the gastrointestinal tract and vomiting may occur early, activated charcoal is not indicated.

**Stabilization and Supportive Care**

Supportive care with fluid resuscitation is the mainstay of treatment for patients symptomatic after chlorophenoxy herbicides.

**Enhanced Elimination**

In the rare event of a critically ill patient (patients requiring ventilator, hemodynamic support, and those with seizures, hyperthermia, or significant metabolic derangements) who presents after chlorophenoxy herbicide poisoning, urinary alkalization or hemodialysis can be used to enhance elimination.10

**Antidote Therapy**

There is no antidote for chlorophenoxy herbicide toxicity.

**Disposition**

A patient who presents with muscular symptoms after chlorophenoxy herbicide toxicity should be admitted and carefully monitored for progression of symptoms. A patient who presents asymptomatic is monitored for 6 hours. If no symptoms develop, the patient can be safely discharged home.

**BIPYRIDYL HERBICIDES**

The bipyridyl (also called dipyridyl) herbicides, paraquat and diquat, are extremely effective contact herbicides that are widely used throughout the world. Paraquat is particularly toxic to humans and is under strict regulation in the United States. Diquat is less toxic and is subject to less regulation.

**Principles of Toxicity**

Paraquat causes the production of superoxides created during cyclic oxidation-reduction reactions in tissues. This causes oxygen radical damage that results in cell death.11 Paraquat selectively concentrates in the lungs, regardless of the route of exposure, because of an uptake mechanism in alveolar cells. High concentration of oxygen in the lungs increases the extent of paraquat-induced oxygen radical injury; therefore, the lungs are the major target organs in paraquat poisoning. Paraquat exposure can lead to adult respiratory distress syndrome, progressive pulmonary fibrosis, and respiratory failure. Paraquat damages other organ systems by the same oxygen radical injury effect, including the liver, kidneys, heart, and central nervous system. Diquat has a similar mechanism of action but does not accumulate in the lung as does paraquat. Diquat concentrates in the kidneys and often results in renal failure. Paraquat is absorbed through the skin, gastrointestinal tract, and respiratory tract. Diquat is poorly absorbed through intact derms.

**Clinical Features**

Paraquat and diquat are corrosive and can cause vomiting and caustic injury to the oropharynx, esophagus, and GI tract. Dermal exposure can cause corrosive injury to the skin. Systemic toxicity from both paraquat and diquat poisoning will often progress to multiorgan failure and death. This is especially true for paraquat, which can be fatal in small amounts. Patients who survive systemic toxicity from paraquat often develop a progressive pulmonary fibrosis 1 to 3 weeks after the exposure. The clinical course, however, is dependent on the dose of the exposure.

**Differential Diagnoses**

Bipyridyl herbicides are corrosive, and the differential diagnosis encompasses other caustic agents (such as, acids and alkalis), insecticides (organophosphates and carbamates), and pulmonary toxic chemotherapy agents (such as, bleomycin). The subsequent systemic toxicity and multiorgan failure with bipyridyl herbicide poisoning could be attributable to other sources of similar symptoms, such as sepsis and acute respiratory distress syndrome (ARDS).

**Diagnostic Testing**

The cornerstone of diagnosing bipyridyl herbicide poisoning lies in the history of exposure. There is a colorimetric urine test to detect diquat and paraquat in urine that can be useful but is not readily available in the United States. Serum concentrations of bipyridal herbicides can be measured but are generally not available in the timeframe useful in the ED; however, the concentration paired with the time of ingestion can be used for mortality prognostication.

Multiorgan failure is possible after bipyridal herbicide poisoning. Laboratory evaluation for respiratory, renal, hepatic, metabolic, and cardiovascular toxicity is indicated. Serial chest radiographs and arterial blood gases are recommended for symptomatic patients.

**Management**

**Decontamination**

Dermal exposure should be treated by removing soiled clothing and washing the skin with water. In general, gastrointestinal decontamination is not indicated in the case of caustic ingestions. Because bipyridyl herbicides, particularly paraquat, can cause systemic toxicity in small amounts, gastrointestinal decontamination may be warranted in these cases of ingestion. We recommend at least 100 g activated charcoal or Fuller’s earth (in certain international settings) if the patient presents early within 1 hour of the ingestion, because this toxicity has high morbidity and mortality without any antidotal therapy.

**Stabilization and Supportive Care**

Upper airway corrosive injury can lead to an obstructed airway. Orotracheal intubation is necessary when there is any concern for such obstruction. Because of the oxygen radical damage, supplemental oxygenation should target oxyhemoglobin saturation of 95%, and excessive oxygenation should be avoided. Supportive care for multiorgan failure is indicated based on the clinical circumstances.
Enhanced Elimination
The use of hemodialysis to increase the elimination of paraquat or diquat is controversial. If renal failure, metabolic acidosis, or electrolyte imbalance develops as a result of the poisoning, dialysis is indicated.

Antidote Therapy
There is currently no specific antidotal therapy for bipyridyl herbicide poisoning. Antioxidants, immune modulators, and corticosteroids have been incompletely evaluated as options for therapy to prevent the delayed pulmonary fibrosis. There is currently insufficient data to recommend specific antidotal treatment in the ED.

Disposition
Due to potential high lethality, patients presenting with bipyridyl poisoning require admission to an ICU setting.

PYRETHRIN AND PYRETHROID INSECTICIDES
Pyrethrins are naturally occurring insecticides derived from the chrysanthemum plant. Pyrethroids are synthetic derivatives of pyrethrins that are more stable in the environment.

Principles of Toxicity
In humans, pyrethrins block voltage-gated sodium channels, voltage-gated calcium channels, and the chloride channels on GABA receptors. Toxicity in humans, however, is not common. Pyrethrins and pyrethroids are used both as commercial insecticides and pharmaceutically to treat human infestations of scabies and lice (e.g., permethrin). Pyrethrins and pyrethroids are poorly absorbed dermally but are well absorbed via gastrointestinal and respiratory routes.

Clinical Features
Toxicity from pyrethrins and pyrethroids is rare. Sensitivity reactions can be seen with exposure. Skin exposure can result in erythema. Inhalation can result in rhinitis, sneezing, oral mucosa irritation, cough, dyspnea, wheezing, and chest pain. Nausea, vomiting, abdominal pain, and diarrhea can occur after ingestion. With massive ingestions, the patient is at risk for neurological symptoms, such as numbness, tremors, ataxia, paralysis, or seizures.

Differential Diagnoses
Sensitivity reactions seen with exposure to pyrethrins and pyrethroids can mimic allergic reactions or contact dermatitis from other etiologies.

Diagnostic Testing
There are no laboratory or diagnostic tests specific to poisoning from pyrethrins and pyrethroids in the ED setting.

Management
Decontamination
In the case of dermal exposure, clothing should be removed and skin washed with water.

Stabilization and Supportive Care
Skin reactions should be treated symptomatically with histamine blockers, such as diphenhydramine. Wheezing should be treated with beta agonists. Neurologic symptoms can be treated with benzodiazepines as needed (lorazepam, 1 to 2 mg IVP; diazepam, 5 to 10 mg IVP).

Enhanced Elimination
There is no role for enhanced elimination in pyrethrin and pyrethroid poisoning.

Antidote Therapy
There is no antidotal therapy for pyrethrin and pyrethroid poisoning.

Disposition
Most cases of pyrethrin and pyrethroid exposure will not demonstrate signs of toxicity and can be safely discharged from the ED. Patients with massive ingestions should be observed for up to 24 hours for the development of neurologic symptoms. Any patient with neurologic symptoms should be admitted to a monitored setting.

GLYPHOSATE
Glyphosate (Roundup) is one of the most commonly used pesticides in the United States. It is a non-selective, contact herbicide that interferes with amino acid synthesis in plants but not in humans.

Principles of Toxicity
Glyphosate is poorly absorbed dermally. It is absorbed through the gastrointestinal tract. Concentrated solutions (41%) can cause mucosal injury. The residential concentration is 1%. Human acute toxicity is thought to be due to the surfactant included in the glyphosate preparation. Unintentional ingestion of glyphosate generally results in mild gastrointestinal symptoms. Hypotension, renal failure, respiratory distress, and death can occur from intentional, massive ingestions.

Clinical Features
Patients who present with dermal exposure to glyphosate will likely have no signs of toxicity. Sensitivity reactions can be seen with exposure. Skin exposure can result in erythema. Inhalation can result in rhinitis, sneezing, oral mucosa irritation, cough, dyspnea, wheezing, and chest pain. Nausea, vomiting, abdominal pain, and diarrhea can occur after ingestion. With massive ingestions, the patient is at risk for neurological symptoms, such as numbness, tremors, ataxia, paralysis, or seizures.

Differential Diagnoses
Sensitivity reactions seen with exposure to pyrethrins and pyrethroids can mimic allergic reactions or contact dermatitis from other etiologies.

Diagnostic Testing
There are no laboratory or diagnostic tests specific to poisoning from pyrethrins and pyrethroids in the ED setting.

Management
Decontamination
In the case of dermal exposure, clothing should be removed and skin washed with water.

Enhanced Elimination
The use of hemodialysis to increase the elimination of paraquat or diquat is controversial. If renal failure, metabolic acidosis, or electrolyte imbalance develops as a result of the poisoning, dialysis is indicated.

Antidote Therapy
There is currently no specific antidotal therapy for bipyridyl herbicide poisoning. Antioxidants, immune modulators, and corticosteroids have been incompletely evaluated as options for therapy to prevent the delayed pulmonary fibrosis. There is currently insufficient data to recommend specific antidotal treatment in the ED.

Disposition
Due to potential high lethality, patients presenting with bipyridyl poisoning require admission to an ICU setting.

PYRETHRIN AND PYRETHROID INSECTICIDES
Pyrethrins are naturally occurring insecticides derived from the chrysanthemum plant. Pyrethroids are synthetic derivatives of pyrethrins that are more stable in the environment.

Principles of Toxicity
In humans, pyrethrins block voltage-gated sodium channels, voltage-gated calcium channels, and the chloride channels on GABA receptors. Toxicity in humans, however, is not common. Pyrethrins and pyrethroids are used both as commercial insecticides and pharmaceutically to treat human infestations of scabies and lice (e.g., permethrin). Pyrethrins and pyrethroids are poorly absorbed dermally but are well absorbed via gastrointestinal and respiratory routes.

Clinical Features
Toxicity from pyrethrins and pyrethroids is rare. Sensitivity reactions can be seen with exposure. Skin exposure can result in erythema. Inhalation can result in rhinitis, sneezing, oral mucosa irritation, cough, dyspnea, wheezing, and chest pain. Nausea, vomiting, abdominal pain, and diarrhea can occur after ingestion. With massive ingestions, the patient is at risk for neurological symptoms, such as numbness, tremors, ataxia, paralysis, or seizures.

Differential Diagnoses
Sensitivity reactions seen with exposure to pyrethrins and pyrethroids can mimic allergic reactions or contact dermatitis from other etiologies.

Diagnostic Testing
There are no laboratory or diagnostic tests specific to poisoning from pyrethrins and pyrethroids in the ED setting.

Management
Decontamination
In the case of dermal exposure, clothing should be removed and skin washed with water.
assess for hyperkalemia. A creatinine concentration assesses for renal injury. If respiratory distress is present, a chest radiograph should be performed. We recommend measuring acid-base status with a venous or arterial blood gas to assess extent of respiratory compromise and for comparison with future measurements to ascertain whether the patient is improving or deteriorating.

Management

Decontamination

With dermal exposure, remove the clothing and wash the skin with water. Gastrointestinal symptoms are generally present with significant ingestions, and activated charcoal is not indicated.

Stabilization and Supportive Care

The mainstay of management of acute glyphosate exposure is supportive care. Provide airway management and cardiovascular support as indicated by the symptom profile. Hyperkalemia can be managed by usual measures.

Enhanced Elimination

There is no role for enhanced elimination in the management of glyphosate poisoning.

Antidote Therapy

There is no antidote for glyphosate poisoning.

Disposition

Patients who demonstrate symptoms after glyphosate ingestion should be admitted for further management. Patients who present after unintentional exposures of small amounts or low concentrations of glyphosate can be discharged from the ED after a 6-hour observation period.

DEET

DEET, or N,N-diethyl-m-toluamide, is not technically a pesticide. It is the most widely used insect repellent used throughout the world. DEET is available in concentrations ranging from 5% to 100%, and it primarily repels mosquitoes. The American Academy of Pediatrics recommends 30% as the maximum concentration for use in infants and children and does not recommend use of DEET in infants younger than 2 months old. It is available as lotions, aerosols, pump sprays, roll-on applicators, and impregnated towelettes. Concentrated DEET solutions (up to 100%) can cause plastic products, such as sunglasses, to melt on contact.

Principles of Toxicology

DEET is lipid soluble and is well absorbed when applied to the skin or ingested. Repeated exposure, skin wounds or abrasions, sweating, and elevated skin temperature increase absorption. DEET affects the central nervous system at the GABA receptors in humans.

Clinical Features

Most exposures to DEET result in no or minimal symptoms. Prolonged skin contact may lead to contact dermatitis, and prolonged contact with higher concentrations can lead to skin blisters. Ingestion of DEET can result in nausea, vomiting, and oral mucosal irritation. Ingestion or excessive skin exposure can lead to headache, liver injury, lethargy, respiratory depression, seizure, and coma.

Differential Diagnoses

The differential diagnosis for DEET poisoning includes any infectious, toxicological (pesticides, organophosphates, carbamates), metabolic, or neurologic abnormality that could cause seizures and depressed mental status.

Diagnostic Testing

There is no specific test for DEET poisoning that is useful in the ED.

Management

Decontamination

In patients with excessive or prolonged skin exposure to DEET, wash the skin with water. Gastrointestinal decontamination has no role in DEET ingestions because of rapid absorption and the potential for seizure activity.

Stabilization and Supportive Care

Supportive care is the mainstay of treatment for a DEET-poisoned patient. Seizures should be treated with benzodiazepines (lorazepam, 1 to 2 mg IVP; diazepam 5 to 10 mg IVP) and are generally self-limited.

Enhanced Elimination

There is no role for enhanced elimination with DEET exposure.

Antidote Therapy

There is no antidote for DEET poisoning.

Disposition

Any patient with acute neurologic symptoms after DEET exposure should be admitted. An asymptomatic patient after an oral ingestion or a patient with localized skin reaction can be discharged from the ED after a 6-hour observation period.

RODENTICIDES

There are hundreds of rodenticides available throughout the world with variable toxicity (Table 157.4). Rodenticides are implicated in self-harm attempts, malicious poisonings, and accidental ingestions. In the United States, anticoagulants, or superwarfarin-type are the most common (over 90% of exposures). They are long-acting anti–vitamin K anticoagulants. Examples are brodifacoum, diphacinone, bromadiolone, chlorophacinone, and difenacoum.

Principles of Toxicology

Superwarfarins competitively inhibit vitamin K and hepatic synthesis of vitamin K–dependent coagulation factors II, VII, IX, and X. These anticoagulants can also damage capillary walls, increasing permeability and fragility, worsening any bleeding. Effects are prolonged in these long-acting anticoagulants—half-life of 156 hours versus 17 hours in first generation warfarins, leading to toxic effects that can last for months. In overdose,

*Modified from the original by Jack Snyder, MD.

ABG: Arterial blood gas; ARDS, acute respiratory distress syndrome; BUN/Cr, blood urea nitrogen/creatinine; CNS, central nervous system; CPK, creatine phosphokinase; CV, cardiovascular; DM, diabetes mellitus; ECG, electrocardiogram; GI, gastrointestinal; ICU, intensive care unit; IVF, intravenous fluids; LFT, liver function test; MRI, magnetic resonance imaging; PNU, N-3-pyridylmethyl-N′-p-nitrophenyl urea; PPE, personal protective equipment; SMFA, sodium monofluoroacetate; TCA, tricarboxylic acid; UA, urine analysis.

Elimination occurs via zero-order kinetics. Toxic effects can be seen in adults ingesting as little as 1 mg. All significant toxicological exposures are via ingestion, and all warfarins are well absorbed orally.

**Clinical Features**

Initially, patients can by asymptomatic and remain so as late as 72 hours after ingestion, even in large ingestions. Alternatively, signs of gastrointestinal irritation can predominate early in the course of poisoning, and symptoms appear as early as 8 hours after exposure. They can then present with bleeding anywhere, such as ecchymosis, epistaxis, hemarthrosis, gingival bleeding, dysmenorrhea, and hematuria. Life-threatening effects are massive gastrointestinal bleeding and intracranial hemorrhage.

**Differential Diagnoses**

Supratherapeutic doses of warfarin, advanced stages of hepatic failure, disseminated intravascular coagulation, hemophilia, and other bleeding disorders can present with similar bleeding symptoms.

**Diagnostic Testing**

With history, suspicion, or overt bleeding, measure hemoglobin/hematocrit, platelets, prothrombin time (PT)/international normalized ratio (INR), partial thromboplastin time (PTT), obtain blood type, and screen as well as crossmatch (if active bleeding). PT/INR might not be abnormal until 48 hours after ingestion; a normal INR at 48 hours essentially excludes a significant ingestion. Although most of these poisons are not commonly measurable,
brodifacoum level is available at many reference labs (<4 to 10 ng/mL is normal and should not cause coagulopathy).

Management

Decontamination

If a patient presents within 1 hour after reported massive ingestion of superwarfarin, we recommend oral activated charcoal in a 10:1 activated charcoal to poison ratio. If the dose ingested is unknown, 100 gm is an acceptable dose. Do not perform gastric lavage, because in addition to existing risks of this method of decontamination, severe gastrointestinal bleeding is added.

Stabilization and Supportive Care

With massive blood loss, fluid resuscitation and transfusion is necessary. RBCs to replace blood loss, fresh frozen plasma to improve coagulation profile, and four-factor prothrombin complex concentrate (PCC) are proven to be beneficial and are considered first-line treatment. Another option shown to be beneficial is recombinant activated factor VII.

Enhanced Elimination

There is no role for enhanced elimination in superwarfarin toxicity.

Antidote Therapy

Vitamin K₁, as opposed to K₃ or K₄, is the preferred antidote, or reversal agent, because other forms are not effective and have potential for toxicity. Although vitamin K₁ will reliably reverse anticoagulation, it should not be given prophylactically; toxicity is determined by derangement in INR. This therapy requires 6 hours to take effect and, therefore, is not used for immediate reversal. This pharmacokinetic principle is responsible for the usual vitamin K dosing regimen of every 6 hours. Prolonged treatment with doses as high as 800 mg daily have been required in massive overdoses.

Disposition

The majority of patients with small warfarin-based rodenticide ingestions (eg, children tasting 2 to 3 pellets) can be discharged home with outpatient follow-up in 48 to 72 hours. Patients presenting with reported large intentional ingestion of superwarfarins (ie, an entire box or bait tray) should be admitted for at least 48 hours, at which time an INR should be checked (minimum time after ingestion to check INR is 2 days). In patients with coagulopathy, admission is required until all bleeding has subsided and the patient is maintained on a vitamin K regimen for desired INR. (This depends on comorbid conditions.) On an outpatient basis, these patients may require monitoring of their coagulation profile for 4 to 6 weeks with the longer-acting superwarfarin products.

KEY CONCEPTS

- Organophosphates cause symptoms by accumulation of acetylcholine.
  - Treat cholinergic symptoms with atropine.
  - Reverse the inhibition of acetylcholinesterase with oximes.
- Aging, which results in prolonged toxicity, occurs with organophosphate poisoning, but not with carbamates.
- Chlorinated hydrocarbons can present with seizures and cardiac toxicity.
- Substituted phenols are found in weight loss products and exert their toxicity by uncoupling oxidative phosphorylation.
  - They can cause cardiac, liver, and renal injury.
- Chlorophenoxy compounds cause muscular injury.
  - Measure creatinine kinase; assess for acute rhabdomyolysis, kidney injury, and liver injury.
- Bipyridyl compounds cause pulmonary and renal injury.
  - Measure creatinine kinase; assess for acute rhabdomyolysis, kidney injury, and liver injury.
- Diquat causes renal injury.
- Pyrethrins and pyrethroids cause local dermatologic symptoms.
- Glyphosate
  - Acute toxicity is likely related to the surfactant included in the product.
- DEET should not be used in infants younger than 2 months old.
- DEET in concentrations of more than 30% should not be used in children and may result in neurotoxicity and self-limited seizure activity if used in excessive amounts.
- Most rodenticide exposures will be superwarfarin compounds.
  - For large exposures, INR should be checked at a minimum of 2 days after ingestion.
  - Vitamin K should be used for reversal; blood products should be used for active bleeding.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Physostigmine can be used as an antidote in anticholinergic syndrome. Physostigmine and pralidoxime are used to reverse cholinesterase activity. (Pralidoxime use for carbamate poisoning is controversial.) Cyproheptadine is an antihistamine that can be used in serotonin syndrome. Treatment for organophosphate or carbamate pesticide. Treatment for organophosphate or carbamate pesticide includes atropine to reverse the cholinergic effects and pralidoxime to restore cholinesterase activity.

157.1. A 37-year-old man arrives at the emergency department (ED) after exposure to an organophosphate. He is severely symptomatic, and atropine is given. When should atropine treatment be discontinued?

A. After 100 mg has been given
B. When fasciculations stop
C. When mydriasis occurs
D. When secretions have stopped
E. When tachycardia occurs

**Answer:** D. Patients with organophosphate poisoning may require very large doses of atropine (up to 500 mg). Proper dosing is 1 or 2 mg intravenously with doubling of the dose every 5 minutes until the drying of secretions. Atropine has no effect at the neuromuscular junction. Mydriasis may occur before secretions have dried. Tachycardia is likely, but it is not a contraindication for continued atropine treatment. The tachycardia often improves as the pulmonary status improves.

157.2. A 30-year-old agricultural worker arrives at the emergency department (ED) with confusion, abdominal pain, nausea, vomiting, and shortness of breath. His coworkers report that he was spraying plants with an insecticide. The patient’s vital signs are significant for hypotension, bradycardia, and tachypnea. Physical examination reveals miosis, wheezing, vomiting, diarrhea, and urinary incontinence. Which of the following combinations of medications should be given to this patient?

A. Atropine and cyproheptadine
B. Atropine and phystostigmine
C. Atropine and pralidoxime
D. Cyproheptadine and phystostigmine
E. Phystostigmine and pralidoxime

**Answer:** C. This patient has symptoms of the cholinergic syndrome (SLUDGE symptoms) and was likely exposed to an organophosphate or carbamate pesticide. Treatment for organophosphate and carbamate poisoning includes atropine to reverse the cholinergic effects and pralidoxime to restore cholinesterase activity. (Pralidoxime use for carbamate poisoning is controversial, but because it is often unclear what exact pesticide was used, treatment with pralidoxime is generally recommended.) Cyproheptadine is an antihistamine that can be used in serotonin syndrome. Phystostigmine can be used as an antidote in anticholinergic syndrome.

157.3. A 4-year-old boy arrives at the emergency department (ED) after drinking a medication that was being used to treat his sister’s head lice. An unknown amount was consumed, and the bottle is not available. The patient’s only complaint is of nausea. Vital signs and physical examination findings are normal. Which of the following symptoms should be anticipated?

A. Gastrointestinal hemorrhage
B. Hallucinations
C. Hypotension
D. Paralysis
E. Seizure

**Answer:** E. Lindane is a chlorinated hydrocarbon insecticide that is used for the topical treatment of head lice and scabies. It is rapidly absorbed and can result in difficult-to-control seizures requiring high doses of benzodiazepines or barbiturates and that may require sedation, paralysis, and intubation. Because lindane is a hydrocarbon, it can sensitize the cardiac membrane and predispose to ventricular dysrhythmias. It can also cause pulmonary compromise if it is aspirated.

157.4. An 18-year-old woman arrives at the emergency department (ED) complaining of feeling generally weak. She reports reading online about a pesticide that can help in weight loss, and she has recently tried this. Her vital signs are: blood pressure, 110/70 mm Hg; heart rate, 121 bpm; respiratory rate, 22 rpm; and temperature, 104°F (40.0°C). Her physical examination reveals dry mucous membranes and yellow staining on her abdomen. Which of the following laboratory findings can you anticipate?

A. Hypoglycemia
B. Hypokalemia
C. Hyponatremia
D. Hypoxia
E. Methemoglobinemia

**Answer:** A. Substituted phenols, such as dinitrophenol, are pesticides that uncouple oxidative phosphorylation. This causes an increased metabolism, which in turn consumes glucose and generates heat, often causing an increased body temperature. For this reason, they have been used as diet aids. They can be applied topically, and the yellow skin staining is pathognomonic for this condition. Lindane is a chlorinated hydrocarbon insecticide that is used for the topical treatment of head lice and scabies. It is rapidly absorbed and can result in difficult-to-control seizures requiring high doses of benzodiazepines or barbiturates and that may require sedation, paralysis, and intubation. Because lindane is a hydrocarbon, it can sensitize the cardiac membrane and predispose to ventricular dysrhythmias. It can also cause pulmonary compromise if it is aspirated.
157.5. What organ system is most affected by paraquat ingestion?
   A. Cardiac
   B. Gastrointestinal
   C. Nervous
   D. Pulmonary
   E. Renal

**Answer:** D. Paraquat is concentrated in the lungs and directly damages the alveolar capillary membrane. This results in surfactant loss, adult respiratory distress syndrome, pulmonary fibrosis, and respiratory failure and is accelerated with supplemental oxygen. All the other organ systems listed are affected but to a much lesser degree.

157.6. A patient arrives at the emergency department (ED) after an intentional paraquat ingestion complaining of severe mouth, throat, and chest pain. What potentially fatal complication of paraquat ingestion should be suspected?
   A. Aortic dissection
   B. Esophageal rupture
   C. Myocardial infarction
   D. Pneumothorax
   E. Pulmonary embolism

**Answer:** B. Paraquat is extremely corrosive and can cause severe burns to the oropharynx, as well as to the esophagus. Frequently, esophageal rupture occurs, leading to mediastinitis and death. None of the other listed conditions occurs with any frequency in paraquat poisoning.

157.7. How do pyrethrins cause toxicity?
   A. Allergic reactions
   B. Bone marrow suppression
   C. Cardiovascular instability
   D. Inhibition of coagulation
   E. Uncoupling of oxidative phosphorylation

**Answer:** A. Pyrethrins are naturally occurring substances from the yellow chrysanthemum and commonly cause allergic reactions in humans. These reactions can be mild or life-threatening with bronchoconstriction and laryngeal edema. They also affect gamma-aminobutyric acid (GABA)-mediated chloride channels in the nervous system, but this typically results in only a mild headache and paresthesias.

157.8. DEET is a commonly used insect repellant that can cause contact dermatitis and more severe neurologic complications, including seizures with high doses that are absorbed through the skin. Which of the following methods will minimize DEET absorption through the skin?
   A. Apply to skin at night
   B. Cover skin with clothing
   C. Expose skin to direct sunlight
   D. Keep skin dry
   E. Remove from skin with oil-based products

**Answer:** D. DEET absorption and toxicity increase with repeated applications, with increased ambient temperatures, with sweating, when it is applied to abraded or thin skin, and when it is covered with tight-fitting clothing. Oils or lipophilic substances applied to the skin also increase absorption of DEET.
PLANTS

PRINCIPLES OF TOXICITY

The nutritional, therapeutic, psychoactive, and toxic properties of botanicals have made their usage pervasive since antiquity. The earliest documented use of plants for medicinal purposes can be found in Sumerian clay tablets that describe the use of over 200 different plants in the treatment of various maladies. Ancient Greeks recognized the lethal effects of botanicals, sentencing Socrates to death by ingestion of a hemlock-based liquid. The recreational abuse and medicinal use of opium poppies highlight the wide-ranging role that plants have played throughout history.

Exposures to plants comprise over 45,000 calls nationally to United States poison centers, with approximately 65% involving patients younger than 6 years old. Over 85% of plant exposures are accidental ingestions. The overwhelming majority of plant exposures result in minimal toxicity and death is exceedingly rare.1,2 Plant exposures reported to United States poison centers have been decreasing over the past three decades, ranking third and comprising 9% of all exposures in 1983, but ranking 17th and making up only 2.5% of all exposures in 2010.3 The most common plant exposures resulting in severe and occasionally fatal poisonings involve those with anticholinergic, antimitotic, cardiotoxic, or convulsive properties.4

CLINICAL FEATURES

The vast majority of plants are considered non-toxic (Table 158.1). However, serious toxicity can result from certain plant exposure (Table 158.2). Toxicity does not correlate well with taxonomy, and plants within the same genera may have varying toxic profiles. Further complicating matters, the severity of exposure may depend on the method of ingestion (ie, chewed or swallowed) and which part of the plant was ingested.4 For example, although all parts of the water hemlock plant are considered toxic, cicutoxin is most concentrated in the root of the plant. The majority of serious or fatal outcomes occur in the adult population intentionally ingesting botanicals for suicidal or recreational intent.4 A focused history and physical examination should be aimed at identifying the involved plant and any toxidrome common to botanical exposures.

DIFFERENTIAL DIAGNOSES

Plant ingestions presenting with vomiting and diarrhea should be differentiated from food poisoning, viral or bacterial gastroenteritis, and pesticide poisoning (often sprayed on plants). Those patients presenting with altered mental status should be differentiated from patients co-ingesting hallucinogenic, stimulant, or opioid drugs of abuse.

DIAGNOSTIC TESTING

Although measurement of specific concentrations of botanical toxins are not routinely available at most institutions, evaluation of electrolytes, complete blood count, liver transaminases, and renal function should be performed in patients with potentially toxic exposures. An electrocardiogram (ECG) and cardiac monitoring should be performed to identify any potential dysrhythmias specific to certain plant classes (eg, anticholinergic, cardiac glycosides). Efforts are made at botanical identification to determine potential toxicity. Patients should not be routinely relied upon for botanical identification. Mistaken identification by patients and family members is a frequent cause of accidental ingestions of toxic botanicals and can lead to inappropriate dispositions from the emergency department (ED).5,6 Furthermore, most emergency medical staff struggle to correctly identify even common house plants. Instead, family members or friends should be asked to bring in or send digital photographs of the involved plant, which can then be compared to reliable reference photographs or referred to local botanical experts or poison centers for proper identification.7,8

MANAGEMENT

There is no role for gastric emptying in the ED management of botanical poisoning. There likewise is no evidence of clinical benefit from activated charcoal, and we do not recommend its routine use in the setting of botanical poisoning. A few exceptions can be made for those who present within 1 hour of ingestion of a potentially life-threatening exposure and can be found in Table 139.12.

There are few antidotes that have been shown to be effective in botanical poisonings. In most exposures, information and identification of the plant is not immediately known, and treatment should be focused on symptom-based, supportive care. This includes maintenance of a patent airway, intravenous (IV) fluids and vasopressors for hypotension, active cooling for hyperthermia, and benzodiazepines for agitation and seizures. Management of specific categories of botanicals is outlined in the following sections.

DISPOSITION

Any patient with signs of severe toxicity, especially those involving the cardiovascular and neurologic systems, should be managed in the ED until symptoms and signs are resolving, or admitted to an intensive care setting. Patients with exposure to unknown plants can be discharged after 6 hours of observation if they are hemodynamically stable and otherwise asymptomatic. This period of observation can be extended to as long as 24 hours if preexisting cardiovascular medical problems exists or an exposure to a plant of serious toxicity is suspected.9

PLANT CATEGORIES

Anticholinergics

Principles of Toxicity

*Datura stramonium* (Jimson weed, angel’s trumpet) (Fig. 158.1) and *Atropa belladonna* (deadly nightshade) are the most frequently encountered plants with anticholinergic toxins. They contain scopolamine, hyoscyamine, and atropine. All parts of the plant contain toxic alkaloids, but they are most concentrated in the seeds of *D. stramonium* and the fruit and leaves of *A. belladonna*.

Clinical Features

Ingestion can cause an antimuscarinic syndrome of agitation, diminished gastrointestinal (GI) motility, dry skin, flushing, hallucinations, hyperthermia, mydriasis, tachycardia, and urinary

Diagnostic Testing

Symptomatic patients with altered mental status, hyperthermia, and tachycardia merit a screening ECG to assess corrected QT (QTc) and QRS intervals, serum electrolytes, glucose, creatine phosphokinase (CPK), and renal function.

Management

Management is based on supportive care, including active cooling for hyperthermia and benzodiazepines for agitation. Recommended agents include diazepam, 5 to 10 mg IV, or lorazepam, 1 to 2 mg IV. Additional doses can be administered every 10 minutes until the patient is calm and able to cooperate with care. The use

*Cardioactive steroid.  
GI, Gastrointestinal.
of a cholinesterase inhibitor, such as physostigmine, is recommended for severe toxicity refractory to benzodiazepines (see Chapter 145).12

Disposition
Mildly symptomatic patients can be observed in the ED for 6 to 8 hours and discharged from the ED. Severely poisoned patients with refractory antimuscarinic symptoms should be admitted to a monitored setting for 24 hours.

Antimitotic Toxins
Principles of Toxicity
Colchicum autumnale is also known as autumn crocus, meadow saffron, or wild saffron, and contains the toxic alkaloid, colchicine. Colchicine inhibits microtubule formation, leading to disruption of mitosis, intracellular transport mechanisms, and cell structure. C. autumnale is often mistaken for Allium ursinum (wild garlic), leading to fatal, unintentional ingestions.2 Pharmaceutical colchicine is most commonly used to treat acute gouty arthritis. Serious toxicity from pharmaceutical colchicine is seen at doses greater than 0.5 mg/kg, and it is invariably lethal at doses of 0.8 mg/kg.

Clinical Features
The clinical course of colchicine poisoning is typically divided into three phases of illness.6,13 The first phase is marked by GI symptoms, such as severe vomiting, diarrhea, hypovolemia, electrolyte disturbances, and abdominal pain. Multi-organ failure ensues in the second phase, with manifestations of cardiac arrhythmia, adult respiratory distress syndrome (ARDS), pancytopenia, liver failure, rhabdomyolysis, and sepsis. Death usually occurs during this second phase. The third phase is recovery from the poisoning.

Differential Diagnoses
Patients presenting in the first phase of illness may be misdiagnosed as gastroenteritis or food poisoning. In the second phase, colchicine poisoning mimics many serious disorders and is treated similarly, with supportive interventions based on the type and severity of the patient’s presentation. Obtaining a history of ingestion is critical to making the correct diagnosis but will not significantly alter the treatment plan. Patients with pancytopenia should be differentiated from patients with sepsis, leukemia, or oncological disorders—obtaining the history of ingestion may avoid invasive testing, such as a bone marrow biopsy.

Diagnostic Testing
Laboratory data should include a complete blood count to assess for pancytopenia. Additional laboratory tests include serum electrolytes, renal and liver function tests, as well as a screening ECG.

Management
There is no specific therapy for colchicine poisoning, and management consists primarily supportive care. There is no commercially available antidote for colchicine poisoning the US, and supportive care is ineffective in those who ingest a lethal dose. Thus, efforts to prevent gastric absorption by administration of activated charcoal should be made for those who ingest a potentially lethal dose of colchicine and present within 1 hour of ingestion.

Disposition
Patients presenting with GI symptoms but normal laboratory testing may be discharged home after 6 to 8 hours of hydration and observation in the ED. Patients with cardiac dysrhythmias, pancytopenia, and/or liver or renal failure require admission to a monitored setting. Patients with pancytopenia require admission and isolation setting to avoid secondary nosocomial infections.

Cardiac Glycosides
Principles of Toxicity
Cardiac glycosides bind to cell transmembrane Na⁺-K⁺-ATPases, which, in turn leads to a rise in intracellular Ca²⁺ concentrations, causing decreased automaticity and increased contractility. Common plants that contain cardiac glycosides include Convallaria majalis (lily of the valley), Digitalis spp. (foxglove) (Fig. 158.2), Nerium oleander (common, pink or white oleander) (Fig. 158.3), and Thevetia peruviana (yellow oleander).

Clinical Features
Similar to digoxin poisoning, patients with exposure to cardiac glycosides can present with GI symptoms, generalized weakness, altered mental status, bradydysrhythmias and tachydysrhythmias, and hypotension. Toxicity and treatment of cardiac glycosides are also discussed in Chapter 147.

Differential Diagnoses
The differential diagnosis of cardiac glycoside plant poisoning is broad and includes pharmaceutical toxicity with digoxin, calcium channel blockers, beta blockers, and clonidine. Additionally, other cardiotoxic plants (discussed later) and other cardiogenic bradydysrhythmias (atrioventricular [AV] blocks and sick sinus syndromes) should be considered. Toxicologic causes of altered

Fig. 158.2. Digitalis purpurea (foxglove). (Courtesy Christopher Lim.)
mental status include, but are not limited to, sedative-hypnotic, anticholinergic, and opioid poisoning. However, infectious, metabolic, traumatic, malignant, and endocrine etiologies can present in a similar fashion.

Visual disturbances can be seen with toxicity from methanol, ethambutol, ethyl chloride, and anti-malarial medications.

No sign or symptom, including dysrhythmia, is unique to digoxin poisoning, so the differential diagnosis is broad. Intrinsic cardiac disease, as well as other cardio toxic drugs, should be considered. Cardioactive steroid poisoning from plants is rare but presents similarly to digoxin toxicity. Common examples include oleander (Nerium oleander, see Fig. 147.2) and lily-of-the-valley (Convallaria majalis, see Fig. 147.3). Aconitine, a sodium-channel opening xenobiotic found in common monkshood (Aconitum napellus), may also mimic digoxin poisoning. Central nervous system (CNS) depression or confusion may be due to various depressant drugs (opioids, major tranquilizers, sedative hypnotic agents) and toxins, as well as infection, trauma, inflammation, and metabolic derangements. Visual disturbances caused by digoxin are binocular and are often not reported by the patient; unfortunately, they are not specific to digoxin poisoning. Methanol, metformin, ethambutol, ethyl chloride, quinine, and other anti-malarial medications are all capable of producing visual disturbances. GI disturbances are common and nonspecific and may be misdiagnosed as gastritis, enteritis, or colitis.

**Diagnostic Testing**

Patients should have an ECG obtained and serum electrolytes measured with attention to potassium because cardiac glycoside poisoned patients are susceptible to hyperkalemia. A serum digoxin concentration can be measured but correlates poorly with the degree of toxicity and should be used only to confirm exposure.

**Management**

The cornerstone of therapy is digoxin-specific antibody fragments and should be administered in any patient displaying serious toxicity (symptomatic bradycardia, sinus arrest or exit block, atrial tachydysrhythmia, ventricular dysrhythmia, second- or third-degree AV block, hypotension, and/or serum potassium level >5.0 mEq/L). Administration of digoxin immune Fab is described in Chapter 147. Cardiac pacing, atropine, and beta-adrenergic agents are without demonstrated benefit and should only be considered adjunctive therapies.

**Disposition**

Symptomatic patients with bradycardia, hypotension, altered mental status, or hyperkalemia are admitted to a monitored setting. Those requiring digoxin-specific antibody fragments should be admitted to an intensive care setting with cardiology or medical toxicology consultation.

**OTHER CARDIOTOXIC PLANTS**

*Rhododendron* species contain grayanotoxin, which can be found in high levels in the honey that is produced from their nectar. Often referred to as “mad honey,” poisonings can present with GI symptoms, hypersalivation, diaphoresis, and cardiac effects. Grayanotoxin binds to cell membrane sodium channels, preventing voltage-dependent inactivation, thereby holding cells in a depolarized state. This is thought to increase vagal tone. The cardiac manifestations mainly consist of brady dysrhythmias (including sinus bradycardia, AV blocks, and atrial fibrillation with slow ventricular response) and hypotension, leading to symptoms of dizziness and syncope. It has even been implicated as a cause of myocardial infarction. In addition to IV fluids for hypotension, atropine and cardiac pacing have been used successfully in the treatment of mad honey toxicity.

*Taxus* species (Fig. 158.4), commonly known as yew, are coniferous trees and shrubs that are often cultivated for ornamental landscaping. They contain several toxic components, including taxine pseudoalkaloids that cause sodium and calcium channel blockade. The most serious effects are on the cardiovascular system, and manifestations include hypotension, dysrhythmias, and cardiac arrest. Management of toxicity is largely supportive. The successful use of extracorporeal circulatory support for severe and refractory cardiotoxicity and hypotension has been reported.

*Aconitum* spp. (monkshood, wolfsbane) contain aconitine and other related alkaloids. Similar to grayanotoxins, aconitine binds and prevents inactivation of voltage-gated sodium channels of
myocardial and neural cells. Thus, the main features of poisoning are neurological (paresthesias, weakness) and cardiovascular (hypotension, dysrhythmias). Management includes supportive care and standard therapy for dysrhythmias.

**Cicutoxin**

**Principles of Toxicity**

Both *Cicuta spp.* (Fig. 158.5) and *Oenanthe crocata* are commonly known as water hemlock, and contain toxins responsible for the hallmark presentation of intractable and life-threatening seizure activity. Seizures are thought to occur from non-competitive gamma-aminobutyric acid (GABA) antagonism.

**Clinical Features**

Initial features of poisoning may include vomiting, abdominal pain, confusion, weakness, and dizziness. Prolonged seizures can further complicate the clinical course, leading to rhabdomyolysis, hyperthermia, acidosis, hypoxia, cerebral edema, and eventual cardiopulmonary arrest.

**Differential Diagnoses**

Water hemlock is often confused for edible plants, leading to unintentional poisonings.

Other neurotoxic agents should be considered including organophosphates, isoniazid (INH), tricyclic antidepressants, methyl xanthines, hypoglycemics, tramadol, sympathomimetic toxicity, and ethanol and benzodiazepine withdrawal. Seizure disorders, head trauma, and brain lesions are also diagnostic considerations.

**Diagnostic Testing**

History is essential to identify the toxin as the cause of the new onset seizure, thus obviating the need for further diagnostic testing. Serum electrolytes will exclude hypernatremia, hyponatremia, hypocalcemia, or hypoglycemia as a cause of the confusion or seizures and hypokalemia as a cause of the weakness. Serum creatine kinase (CK) and creatinine will evaluate for rhabdomyolysis and renal impairment. A toxicology screen, especially a serum ethanol level, also will help identify or exclude alternate causes of the confusion. An ECG should be performed to assess intervals if an electrolyte disturbance or overdose is suspected.

**Management**

The mainstay of management seizure control with benzodiazepines (lorazepam, 1 to 2 mg IV, or diazepam, 5 to 10 mg IV, repeated every few minutes until seizure activity ceases). If seizure activity is not controlled with benzodiazepines, treatment is as for other toxicologic causes of status epilepticus (see Chapter 92).

**Disposition**

Patient with altered mental status and seizures should be admitted to an intensive care setting. Those who are asymptomatic after 6 to 8 hours observation in the ED may be discharged home.

**OTHER TOXIC PLANTS**

**Nicotinic Toxin**

*Conium maculatum* (poison hemlock) (Fig. 158.6), *Nicotiana tabacum* (Fig. 158.7), and *Nicotiana glauca* (wild or tree tobacco) contain alkaloids capable of producing nicotinic-cholinergic poisoning. They contain the toxins coniine (C. maculatum), anabasine (N. glauca) that stimulate nicotinic acetylcholine receptors on the autonomic nervous system and neuromuscular junction.

Clinical effects can include hypersalivation, vomiting, diarrhea, muscle fasciculation, and agitation; toxicity can progress to profound weakness, paralysis, respiratory failure, hypotension, rhabdomyolysis, and renal failure.

There is no specific antidote, and treatment should be aimed at ventilatory support for those with respiratory distress or muscle fatigue and those who cannot adequately oxygenate. Treatment should be continued until resolution of respiratory muscle fatigue and the patient can adequately support their own respirations.

**Raphides**

Raphides are needle-shaped, calcium oxalate crystals and have been observed in over 200 plants. Clinically common plants that contain calcium oxalate crystals include the species from the genera *Dieffenbachia* (dumb cane, mother-in-law plant)
the rare case of respiratory distress with significant airway edema following ingestion of specific raphide plants.

**Toxalbumins**

*Abrus precatorius* (jequirity pea, rosary or prayer bead) and *Ricinus communis* (castor oil plant) contain the toxins abrin and ricin, respectively, that inhibit ribosomal protein synthesis, leading to cell death. Seeds of *A. precatorius* are distinctive, bright red or orange seeds with black caps that are often used in jewelry or rosaries. Castor beans are light brown, mottled with dark brown spots. Seeds or beans swallowed whole with the hard outer shell intact typically prevent absorption of significant toxin.30 Chewed or crushed seeds or beans may release the toxin and cause local toxicity in the GI tract, leading to gastroenteritis, abdominal pain, dehydration, and electrolyte disturbances.30,31 Rarely, abrin or ricin is absorbed systemically, and symptoms may progress to severe neurologic toxicity (seizure, coma, cerebral edema, demyelinating encephalitis), multi-organ failure, and death. Purified ricin derived from the castor bean is highly toxic and lethal in small doses. It has been used as a biologic weapon, implicated in the assassination of Bulgarian journalist Georgi Markov, and more recently, being discovered at a White House mail facility.

There is no effective antidote, vaccine, or other therapy for the treatment of abrin or ricin poisoning. Treatment consists of fluid resuscitation and correction of electrolyte imbalances with neurotoxic symptom precautions.

**MUSHROOMS**

**PRINCIPLES OF TOXICITY**

Mushrooms represent a wide range of species with regional variation. In this section, we consider the mushrooms of toxicologic significance. The categories of poisonous mushrooms are grouped
according to the types of illness or organ-specific toxicity. Another important perspective is that the most common species of toxic mushrooms belong to the GI irritant group and generally do not cause life-threatening illness.\(^{22,33}\) Distinguishing the GI irritant group from the more serious groups is the challenge for the treating emergency clinician.

According to data from 2013 as reported to the American Association of Poison Control Centers, there were a total of 6575 mushrooms ingested. The majority of the ingested mushrooms were never identified (5517). Five mushrooms from the cyclopeptide group, five from the hallucinogenic group, and four from the muscimol-containing group resulted in major effects. There was only one fatality in this database, and it was an unknown mushroom.\(^7\)

**CLINICAL FEATURES**

An important clinical consideration is the onset of symptoms caused by a mushroom. In general, the GI irritants will develop symptoms in the first 2 to 3 hours after ingestion. Some of the most lethal mushrooms will develop symptoms on a delayed basis, such as *Amanita phalloides*, or *Gyromitra esculenta*, at 6 to 8 hours after ingestion.\(^32\) There are some exceptions that are mentioned later.

**DIFFERENTIAL DIAGNOSES**

Many mushrooms are edible and considered delicacies, such as puffballs or morels. However, there are many look-alikes, and foragers must be certain that they identify correct species to avoid illness. The differential diagnosis with mushroom poisoning includes gastroenteritis, pancreatitis, hepatitis, acute renal failure, hallucinogenic poisonings, anticholinergic and cholinergic poisonings, disulfiram toxicity, and food poisoning.

**DIAGNOSTIC TESTING**

Identifying the mushroom ingested is extremely helpful to the treating team. It is beyond a realistic scope for emergency clinicians to be able to identify mushrooms, and it is wise to coordinate with poison control centers and local mycologists to identify mushrooms in real time. Digital identification by sending images to mycologists via a poison control center model has been shown to be accurate in identifying mushrooms.\(^7\) Attempts should be made to secure mushroom identification particularly after a delayed onset of GI symptoms.

Routine testing includes complete blood count, urinalysis, and basic metabolic profile with specific attention to renal function and measures of dehydration. Liver enzyme and tests of liver function should be obtained if cyclopeptide or gyromitrin poisoning is suspected.

**MANAGEMENT**

The general management of mushroom poisoning focuses on symptom-based, supportive care. Management for specific mushroom poisoning is discussed later.

There is no proven outcome benefit from administration of activated charcoal for patients with mushroom ingestion. We recommend activated charcoal only if the patient presents sufficiently rapidly for the activated charcoal to be given within 1 hour of the ingestion if the clinician suspects ingestion of a potentially life-threatening mushroom (eg, cyclopeptide or gyromitrin containing species). We do not recommend gastric emptying by any method. Because many toxic mushrooms can cause vomiting or diarrhea, it is important that these patients are fluid resuscitated and rehydrated until they can tolerate oral liquids and food.

**DISPOSITION**

Patients should be admitted for 24 hours when the ingestion of a potentially life-threatening mushroom poisoning has occurred. For suspected or confirmed GI irritant mushroom ingestion, the patient can be safely discharged home after the GI symptoms are controlled and oral fluids are tolerated.

**MUSHROOM CATEGORIES**

**Hepatotoxic Mushrooms**

**Principles of Toxicity**

The two major categories of mushrooms that can cause life-threatening hepatotoxicity include cyclopeptide-containing mushrooms, such as *Amanita phalloides*, and certain *Leiophyllum* species. The *Gyromitra* species also cause hepatotoxicity but have other symptoms distinct from the cyclopeptide-containing mushrooms.\(^22,33\)

**Clinical Features**

The cyclopeptide-containing mushrooms will cause the onset of GI symptoms 6 to 8 hours after ingestion. This includes nausea, vomiting, diarrhea, and abdominal pain. Over the next 1 to 2 days, the patient will develop increasingly severe hepatic injury and encephalopathy.

**Differential Diagnoses**

In patients with cyclopeptide-containing mushroom toxicity with elevations in liver aminotransferases, bilirubin, partial thromboplastin time (PTT)/international normalized ratio (INR), or creatinine, other sources of injury should be considered, including acute tubular necrosis, rhabdomyolysis, ischemic hepatitis, alcoholic hepatic disease, viral hepatitis, and Wilson disease. Other hepatotoxic considerations include poisoning with acetaminophen, valproic acid, INH, statins, herbal medications, vinyl chloride, and polychlorinated biphenyls.

**Diagnostic Testing**

Evidenced by rising liver enzymes and worsening measures of liver function (rising bilirubin and increased INR). These markers should be followed serially during the hospital course. Also, because patients may develop a hepatorenal syndrome, renal function tests should be measured.

**Management**

Many therapies have been tried for cyclopeptide-containing mushrooms. Initial decontamination with oral active charcoal is recommended if the patient presents within 1 hour of ingestion and has not already vomited. Suggested therapies in the literature that may be immediately available include *N*-acetylcysteine (NAC), high dose penicillin, and early hemodialysis or hemoperfusion. NAC is thought to work via hepatoprotective effects, and animal studies indicate that amatoxins deplete glutathione stores. IV NAC dosing regimens are similar to those administered to acetaminophen poisoned patients (see Chapter 143). High-dose penicillin is thought to work by displacing amatoxin uptake by the hepatocytes. Experimental antidotes, such as thiocyst acid, silibinin, and *polymyxin B*, have been more commonly used in Europe.\(^35,36,40\) Silibinin is currently available as an investigational agent and can be accessed by calling the manufacturer at (866) 520-4412.\(^39\) If a cyclopeptide-containing mushroom has been
ingested, we suggest mobilizing silibinin and calling your regional poison control center to coordinate management and prioritization of agents. Patients who progress to fulminant hepatic failure despite appropriate supportive care may ultimately require liver transplantation. Early consultation with a transplant center should be initiated early in the course of management.

Disposition

Patients showing evidence of severe hepatotoxicity and those at risk for fulminant hepatic failure are admitted to an intensive care unit. These patients require frequent neurologic checks, monitoring of vital signs, and repeated laboratory studies. If a patient presents with established hepatotoxicity, transferring to a tertiary care center that specializes in the management of hepatic failure patients with liver transplant capabilities is advisable.

Gyromitrin-Containing Mushrooms

Principles of Toxicity

Gyromitrin-containing species are also known as the false morel. Like the cyclopeptide-containing mushrooms, these can also cause significant hepatotoxicity but may also cause neurotoxic seizures. The mechanism for seizures is similar to INH by causing deficiency of pyridoxine and inhibiting the action of glutamic acid decarboxylase. This prevents the formation of GABA, an inhibitory neurotransmitter. These mushrooms can also induce some degree of oxidant stress, which can clinically manifest as methemoglobinemia.

Clinical Features

Similar to the cyclopeptide-containing group, gyromitrin mushrooms can cause delayed nausea, vomiting, diarrhea, and hepatotoxicity, but they most notably manifest with generalized seizure activity.

Differential Diagnoses

The highly sought after “true” morel is a mushroom is an edible delicacy and is considered nontoxic. The false morel has a close resemblance and can be found in similar regions. Other causes of seizures and neurotoxicity should be considered, including INH poisoning, sympathomimetic toxicity, intracranial bleeds, brain mass lesions, and underlying seizure disorders. Other causes of methemoglobinemia include nitrate and nitrate containing compounds, local anesthetic agents, dapsone poisoning, and inborn errors in metabolism.

Diagnostic Testing

In patients presenting with seizure activity, obtaining a history of toxic ingestion obviates the need for most diagnostic testing. Because there is potential for hepatotoxicity, serial liver transaminases should be monitored. Serum electrolytes should be monitored for protracted vomiting or diarrhea. A screening methemoglobin level is also recommended.

Management

Management of gyromitrin-induced seizures should include IV pyridoxine, as one would for INH poisoning, with 5 g as an empirical dose (see Chapter 127). Clinically significant methemoglobinemia can be managed with methylene blue, although this is a rare occurrence. (See Chapters 57 and 153 for methylene blue dosing.)

Fig. 158.10. Coprinus atramentarius. (Courtesy Joe McFarland.)

Disposition

Patient with altered mental status and seizures requiring pyridoxine therapy should be admitted to an intensive care setting. Those who are asymptomatic after 6 to 8 hours observation in the ED may be discharged home.

OTHER MUSHROOM CLASSES

Cholinergic Agonists

True cholinergic agonists are rarely encountered in the clinical setting. Clitocybe dealbata, also known as “the sweater,” is one of these mushrooms. If ingested, clinical symptoms of cholinergic excess may be seen. Muscarinic effects recalled by the mnemonic SLUGBAM, can be useful. SLUGBAM stands for Salivation, Lacrimation, Urination (excessive), Gastrointestinal effects (nausea, vomiting, and diarrhea), Bradycardia/bronchorrhea/bronchospasm, Abdominal cramps, and Miosis. Treatment is supportive, but atropine can be used for excessive cholinergic symptoms, precisely as described in Chapter 157. Unlike organophosphates, there is no role for oxime therapy.

Disulfiram Reaction-Inducing Mushrooms

Coprinus atramentarius and other Coprinus species contain the toxin coprine that can inhibit aldehyde dehydrogenase similar to disulfiram. If ingested along with ethanol, it can lead to a disulfiram-like reaction including nausea, vomiting, diarrhea, and flushing. Treatment is generally supportive, including IV hydration and antiemetics, such as prochlorperazine, or ondansetron (Fig. 158.10).

Hallucinogenic Mushrooms

There are a wide variety of mushrooms that can lead to hallucinations. Some common examples include the Psilocybe and Conocybe species. These are direct hallucinogens and contain psilocybin and related compounds. Psilocybin is found in a wide range of mushrooms. These are well known to be purchased online and in “grow at home” kits.

The ibotenic acid and muscimol containing mushrooms can also lead to hallucinations. Amanita muscaria is an important example of this class. Others include Amanita pantherina and Gemmata species. Ibotenic acid acts similar to glutamate and can have excitatory effects. Muscimol has inhibitory effects and works
as a GABA agonist. These mushrooms can be used for their hallucinogenic effect.

Overdose of these mushrooms can lead to dry mouth, dilated pupils, tachycardia, agitation, delirium, and seizures. The mainstay of treatment of hallucinogenic mushrooms is providing a low-stimulus environment where the effects can dissipate. Benzodiazepines are generally effective in treating the agitation and tachycardia (lorazepam, 1 to 2 mg IVP; diazepam, 5 to 10 mg IVP). Antipsychotic agents can be used for prolonged hallucinations not improved with benzodiazepines (eg, haloperidol, 2 to 5 mg).39

Gastrointestinal Irritants

There are hundreds of species of mushrooms that are GI irritants. These mushrooms cause irritation to the GI tract within 2 to 3 hours of ingestion.12,14 Some commonly encountered species of GI irritants include Boletus spp., Chlorophyllum molybdites, Lactarius sp., and Omphalotus sp. Nausea, vomiting, diarrhea, and crampy abdominal pain will be the typical presenting symptoms. The course is generally self-limiting, but care should be taken to monitor patients with prolonged symptoms or with significant fluid losses.

Another consideration with mushrooms ingested that cause GI symptoms is that the mushroom may be contaminated with pesticides or metals. Therefore, the symptoms may not be from the mushroom itself but from the chemical contaminant.

Renal Insufficiency

Two species of mushrooms can potentially lead to direct renal toxicity. In Europe, the Cortinarius species of mushrooms have been associated with renal failure.30 This effect commonly occurs on a delayed basis and as long as 2 weeks after ingestion. Similar to the deadly cyclopeptide and gyromitrin-containing mushrooms, symptoms will begin on a delayed basis. This mushroom is not generally found in the United States.

A more problematic mushroom that is found in the Pacific Northwest is the Amanita smithiana mushroom. The toxin contained in this mushroom is allenic norleucine. This mushroom leads to GI symptoms early after ingestion, and thus violates the general rule of thumb for serious poisoning follows delayed onset of GI symptoms. GI symptoms can begin between 2 and 12 hours after ingestion. Treatment is generally supportive, including fluid bolus followed by maintenance. However, with acute renal failure, metabolic acidosis, and electrolyte imbalances, hemodialysis may be required.

Rhabdomyolysis-Inducing Mushrooms

Another mushroom that can cause toxicity on a delayed basis is from Tricholoma equestre (commonly referred to as the “man on horseback” or “yellow knight” mushroom). It can cause weakness, fatigue, and muscle pain 24 to 72 hours after ingestion. This mushroom can cause clinically significant rhabdomyolysis. Serum CPK levels should be followed to monitor for rhabdomyolysis and development of renal failure. Treatment is supportive with IV hydration and alkalinization therapy.

HERBAL MEDICATIONS

Although much of the world’s population has used herbal products as medicine for centuries, its growing popularity in the United States is a relatively recent trend. Since the passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994, the number of herbal products on the market has sharply increased over twentyfold to over 90,000 in 2014.40 It is estimated that nearly 40 million adults in the United States use herbal products with sales exceeding $5 billion annually.39

PRINCIPLES OF TOXICITY

The DSHEA established herbal products as food; and unlike pharmaceuticals, they are not subject to rigorous regulations and do not need to demonstrate efficacy or safety for commercial sale. As a result, ingredients and their concentrations are often unknown, and controlled clinical trials and toxicologic testing are not routinely performed. Contrasting this, the consumer may believe that herbal medications undergo strict regulation and testing, and they are safer and more efficacious than pharmaceuticals. This misperception, combined with a lack of proper dosing and scheduling regimen, may lead to misuse and over-use of herbal medications. Factors that further contribute to adverse events include inherent toxicity, contamination and adulteration of products, and herb-drug interaction.40,41 Studies show that most people who use herbal medications in addition to prescribed medications will do so without consulting or notifying health care providers.

Clinical research in the area of herb-drug interaction is lacking.42 Most pharmaceutical drugs undergo hepatic biotransformation and inactivation via the cytochrome P450 enzymes. Herb-drug interactions typically stem from alteration of this system, leading to increased or decreased drug concentration. Herbal medications may also affect drug transporters, such a p-glycoprotein, and further modify pharmacodynamics. St. John’s wort (Hypericum perforatum) (Fig. 158.11) induces cytochrome P450 family 3, subfamily A (CYP3A), which metabolizes approximately 50% of available United States pharmaceuticals, leading to decreased drug concentrations.

CLINICAL FEATURES

Many herbal medications possess toxicity inherent to the botanical from which they are derived (Table 158.3). Adverse effects can range from allergic reactions to cardiovascular and hepatic toxicity. The U.S. Food and Drug Administration (FDA) banned the

*SLUGBAM stands for Salivation, Lacrimation, Urination (excessive), Gastrointestinal effects (nausea, vomiting, and diarrhea), Bradycardia/bronchorrhea/bronchospasm, Abdominal cramps, and Miosis.

GI, Gastrointestinal; NAC, N-acetylcysteine.

sale of Ma Huang (Ephedra sinica) in 2004 after reports of serious cardiovascular events and death related to its sympathomimetic effects.52 Many herbal medications, including Germander (Teucrium chamaedrys), Pennyroyal oil (Mentha pulegium and Hedeoma pulegioides), and those containing pyrrolizidine alkaloids are associated with hepatotoxicity.48 Most herbal medications that possess inherent toxicity can have adverse maternal-fetal effects, and we advise against the routine use of herbal medications during pregnancy.

Some herbal medications increase bleeding risk by altering the pharmacokinetics of anticoagulants, such as warfarin, or having a synergistic effect with antiplatelets and anticoagulants.46,47 The concurrent use of several herbal medications, such as St. John's wort, with other serotonergic drugs can potentially contribute to the development of serotonin syndrome.46 Kava-kava (Piper methysticum) and valerian (Valeriana officinalis) have been shown to potentiate GABA-mediated CNS depression of alcohol consumption.

**DIFFERENTIAL DIAGNOSES**

Due to the unregulated nature of herbal medications, contaminants and adulterants are often found and may contribute to toxicity. In addition to fillers and substituents, contamination with heavy metals, pesticides, and other harmful materials have been found in herbal medications. Certain metals are believed to have therapeutic properties.42 Lead is the most commonly reported heavy metal contaminant, but arsenic, cadmium, and mercury poisoning after herbal medication use have been described as well.49-51 Additionally, there are many examples reported in the literature of toxicity from herbal medications adulterated with pharmaceuticals.52

**DIAGNOSTIC TESTING**

Diagnostic studies in patients presenting with herbal medication toxicity include a complete blood count, coagulation profile, serum electrolytes, and glucose, hepatic, and renal function tests. In addition, acetaminophen and salicylate levels should be measured along with urinary heavy metal screens, targeting lead, arsenic, and mercury.

**MANAGEMENT**

Treatment is largely supportive with hydration, bleeding control if coagulopathic, cardiac dysrhythmia treatment, and targeted antidote therapy (eg, NAC, heavy metal chelation therapy; see Chapter 151).

**DISPOSITION**

The majority of patients with herbal medication toxicity will be mildly symptomatic with GI symptoms and normal diagnostic studies. These patients can be observed and hydrated in the ED and safely discharged home. Patients with systemic toxicity including hepatic, renal, cardiac, or multi-organ failure require admission for monitoring and consultation from appropriate specialty services.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
A 52-year-old man presents after ingestion of water hemlock complaining of nausea but no other symptoms. He reports that he ate the water hemlock in a suicide attempt but has since changed his mind. His vital signs and physical examination are normal. What is the most appropriate initial treatment of this patient?

A. General seizure precautions
B. Hemodialysis
C. Neutralization with milk
D. Supportive care only
E. Whole bowel irrigation

Answer: A. Water hemlock is very toxic with fatality rates as high as 70%. Because this patient is at risk for seizures, oral activated charcoal and gastric lavage are contraindicated. Hemodialysis, whole bowel irrigation, and milk are not beneficial. Supportive care is not adequate with water hemlock ingestion. Most deaths are caused by intractable seizures, so this complication should be anticipated.
158.3. Oleander contains cardiac glycosides similar to digoxin. Which of the following should be considered when treating oleander ingestion?
A. Activated charcoal should be avoided.
B. Serum digoxin levels correlate with degree of toxicity.
C. Treatment is supportive.
D. Treatment with digoxin-specific Fab fragments is beneficial, but a higher dose is necessary.
E. Treatment with digoxin-specific Fab fragments is not beneficial.

Answer: D. Treatment is with digoxin-specific Fab fragments, but much higher doses are necessary compared with those needed to treat digoxin toxicity. Activated charcoal may be useful if the ingestion was recent. A serum digoxin level should be measured, but it is not a reliable indicator of level of toxicity. An elevated level confirms oleander ingestion, but a negative level cannot rule out ingestion.

158.4. A husband and wife present to the emergency department (ED) complaining of nausea and vomiting after eating mushrooms that they picked while hiking. They report eating the mushrooms on a salad approximately 1 hour ago. Each is complaining of severe nausea, vomiting, and diffuse abdominal pain. There is no hematemesis. Vitals signs and physical examination are normal. You inform them that they will be symptomatically treated and observed, but there is likely nothing to worry about. Why are you not concerned about their ingestion?
A. Early onset of gastrointestinal (GI) symptoms
B. No hematemesis
C. No right upper quadrant tenderness
D. Normal mental status
E. Normal vital signs

Answer: A. The vast majority of severely toxic mushrooms have delayed onset of symptoms (>6 hours from ingestion). Occasionally, people will ingest two different types of mushrooms—one benign and causing early onset of symptoms and one more toxic. Therefore patients should be observed and rechecked.

158.5. What is the most common cause of death after mushroom ingestion?
A. Gastrointestinal (GI) hemorrhage
B. Heart failure
C. Liver failure
D. Renal failure
E. Respiratory failure

Answer: C. The Amanita species of mushrooms are very toxic and cause fulminant liver failure often necessitating liver transplant. Mushrooms generally do not affect the other listed organ systems.

158.6. A 46-year-old man presents after waking in the night with headache and severe nausea and vomiting. For dinner the night before, he consumed some mushrooms that he had gathered from a nearby forest. He felt fine immediately after dinner. His vital signs are normal. While conducting your physical examination, he begins to seize. Benzodiazepines are administered without improvement. What treatment is indicated?
A. Phenobarbital
B. Phenytoin
C. Propofol
D. Pyridoxine
E. Vecuronium

Answer: D. Most mushrooms do not cause seizures, but gyromitrin-containing mushrooms are an exception. They are commonly mistaken for edible morels, because they look quite similar. They contain an isoniazid (INH)-like toxin that causes seizures. Traditional seizure medications can be used (because they are typically more readily available), but seizures can be intractable until pyridoxine is given.
BARBITURATES

Although barbiturates are still used for management of some seizure disorders, they have long been supplanted as sedatives by the benzodiazepines. Mortality from barbiturate poisoning declined from approximately 1500 deaths per year in the 1950s to fewer than five fatalities in 2013.1

Barbiturates are addictive, producing physical dependence and a withdrawal syndrome that can be life-threatening. Whereas tolerance to the mood-altering effects of barbiturates develops rapidly with repeated use, tolerance to the lethal effects develops more slowly, and the risk of severe toxicity increases with continued use.

Principles of Toxicity

Barbiturates depress the activity of all excitable cells, especially those in the central nervous system (CNS), by enhancing the activity of gamma-aminobutyric acid (GABA), the major central inhibitor. In acute overdose, barbiturates decrease neural transmission in autonomic ganglia, the myocardium, and the gastrointestinal tract and also inhibit the response to acetylcholine at the neuromuscular junction.

The GABAA receptor is a protein complex found on postsynaptic membranes in the CNS. Structurally, it consists of several distinct receptor sites surrounding a chloride ion (Cl−) channel (Fig. 159.1). GABA opens the chloride channel. The resulting flow of Cl− into the cell increases the negative resting potential, hyperpolarizing and stabilizing the membrane. There are separate receptor sites for barbiturates and for benzodiazepines and a third site that binds GABA, ethanol, and meprobamate. Although barbiturates and ethanol can directly increase Cl− conductance, benzodiazepines require the presence of GABA to affect Cl− flow, which may account for the relative safety of benzodiazepines in comparison with barbiturates.

Barbiturates produce dose-related depressive effects ranging from mild sedation to coma and fatal respiratory arrest. In the early stages of intoxication, some patients experience euphoria. Barbiturates have no analgesic effect and can paradoxically increase the reaction to pain at low doses.

Barbiturates act directly on the medulla to produce respiratory depression. In therapeutic doses, this respiratory depression mimics that of normal sleep. Starting with doses approximately three times therapeutic, the neurogenic, chemical, and hypoxic respiratory drives are progressively suppressed. Because airway reflexes are not inhibited until general anesthesia is achieved, laryngospasm can occur at low doses.

Therapeutic oral doses of barbiturates produce only mild decreases in pulse and blood pressure, similar to sleep. With toxic doses, more significant hypotension occurs from direct depression of the myocardium along with pooling of blood in a dilated venous system. Peripheral vascular resistance is usually normal or increased, but barbiturates interfere with autonomic reflexes, which then do not adequately compensate for the myocardial depression and decreased venous return. Barbiturates can precipitate severe hypotension in patients whose compensatory reflexes are already maximally stimulated, such as those with heart failure or hypovolemic shock. Barbiturates also decrease cerebral blood flow and intracerebral pressure. Although hypnotic doses of barbiturates do not affect gastric emptying, higher doses can decrease gastrointestinal smooth muscle tone and peristaltic contractions, delaying gastric emptying.

Barbiturates are classified according to their onset and duration of action (Box 159.1): ultra-short acting (onset immediate after intravenous dose, duration minutes), short acting (onset 10 to 15 minutes after oral dose, duration 6 to 8 hours), intermediate acting (onset 45 to 60 minutes, duration 10 to 12 hours), and long acting (onset 1 hour, duration 10 to 12 hours). Only long-acting preparations have anticonvulsant effects in doses that do not cause sedation. Short- and intermediate-acting preparations are almost completely metabolized to inactive metabolites in the liver, whereas 25% of a phenobarbital (long-acting) dose is excreted unchanged through the kidney.

Barbiturates cross the placenta with fetal levels approaching those of the mother. They are also excreted in low concentration in breast milk. Use during pregnancy is associated with birth defects (category D).

Clinical Features

Mild barbiturate toxicity manifests with drowsiness, slurred speech, ataxia, unsteady gait, nystagmus, emotional lability, and impaired cognition.

In severe acute intoxication, CNS depression progresses from stupor to deep coma and respiratory arrest. Although pupils are usually normal or small and reactive, concomitant hypoxia can cause pupils to be fixed and dilated. Corneal and gag reflexes may be diminished or absent, muscle tone flaccid, and deep tendon reflexes diminished or absent. Flexor (decorticate) and extensor (decerebrate) posturing can occur in patients comatose from barbiturate intoxication. These neurologic signs are variable and do not always correlate with severity of intoxication or depth of coma. A fluctuating level of consciousness is commonly seen. High barbiturate levels depress gastrointestinal motility, delaying drug absorption. As the drug is metabolized and blood levels drop, peristalsis and drug absorption may increase, causing drug levels to rise again.

The life threat in severe barbiturate toxicity is respiratory depression. Because respirations can be rapid but shallow, the degree of hypventilation may not be apparent on clinical examination, and pulse oximetry or capnography may be needed to detect the ventilation compromise.

Hypotension is common in patients with severe intoxication, along with a normal or increased heart rate. Barbiturate overdose is associated with noncardiogenic pulmonary edema. Altered pulmonary capillary permeability can be caused by hypoperfusion, hypoxia, or a direct effect of the drug. Pneumonia due to aspiration may be delayed.

Barbiturate withdrawal syndrome includes tremors, hallucinations, seizures, and delirium (similar to the delirium tremens of
ethanol withdrawal). However, severe withdrawal occurs only after dependence on short- or intermediate-acting barbiturates (eg, pentobarbital, secobarbital, amobarbital, or butalbital). Because these drugs are not commonly used, this syndrome is now very rare.

**Differential Diagnoses**

Mild barbiturate toxicity mimics ethanol intoxication and that of other sedative hypnotic agents, such as benzodiazepines. Alcohol and benzodiazepine toxicity cause less hypotension and respiratory depression than barbiturates, whereas chloral hydrate overdose is marked by greater cardiotoxicity (see later in this chapter). Gamma-hydroxybutyrate (GHB) produces coma similar to that of barbiturates, but resolution of the coma occurs much more rapidly. Opioids cause similar sedation properties but with miosis, whereas barbiturates typically cause mydriasis when deeper stages of coma result in hypoxia. Other common antiepileptic agents (such as, carbamazepine, phenytoin, and valproic acid) will cause sedation similar to barbiturates with acute overdose. As with any patient exhibiting depressed mental status, metabolic causes (such as, hypoglycemia) and intracranial events (such as, cerebral ischemia or hemorrhage) should be excluded.

**Diagnostic Testing**

The therapeutic level of phenobarbital is 15 to 40 µg/mL (65 to 172 µmol/L). A serum level greater than 50 µg/mL can be associated with coma, especially in a patient who is not a chronic user. Levels greater than 80 µg/mL cause potentially fatal respiratory depression. Serial phenobarbital levels can monitor effectiveness of treatment. Other than phenobarbital, barbiturates have high volumes of distribution, so serum levels do not accurately reflect CNS concentrations or correlate with clinical severity. A positive urine screen establishes only qualitative exposure to a barbiturate but does not prove that the drug is present in toxic amounts and should not be relied on to explain decreased mental status.

Chest radiographs can detect noncardiogenic pulmonary edema or aspiration pneumonia. Computed tomography of the head may be helpful in comatose patients with evidence of trauma, focal neurologic signs, papilledema, or uncertain diagnosis to detect other causes of stupor and coma.

Because the electroencephalogram may be silent as a result of barbiturate overdose, no patient should be declared “brain dead” if barbiturates are present at therapeutic levels or higher.

**Management**

Because barbiturates have no specific antidote, the key to managing these patients is supportive care, particularly with respect to the cardiovascular and respiratory systems. Severely intoxicated patients are unable to protect their airway and have decreased ventilatory drive. Supplemental oxygen may suffice for patients with mild to moderate overdose, but intubation is often required. Long-term induced paralysis is rarely necessary, and additional sedation usually is unnecessary for mechanical ventilation. Careful fluid replacement should aim to maintain a systolic blood pressure above 90 mm Hg and adequate urine output. Patients should be monitored for fluid overload and pulmonary edema.

**Gastrointestinal Decontamination**

Gastric emptying by lavage is not indicated. High barbiturate levels depress gastrointestinal motility, delaying drug absorption. As the drug is metabolized and blood levels drop, peristalsis and drug absorption may increase, causing drug levels to rise. Although there is evidence that multidose activated charcoal increases clearance of phenobarbital and may shorten duration of clinical toxicity, there is no evidence it results in improved outcomes over supportive care alone.

**Enhanced Elimination**

Because phenobarbital is a weak acid (pKₐ 7.2), alkalinization of the urine will increase the amount of drug present in ionized form, minimizing tubular reabsorption and increasing drug clearance. Other short- and intermediate-acting barbiturates are not significantly affected by pH changes in this range. Alkalinization may interfere with the ability of the drug to diffuse across intestinal mucosa from the blood into the gut. We agree with a comprehensive review that concluded that there is little clinical role for urine alkalinization in acute barbiturate poisoning.

Although there are insufficient data to determine the true risk-benefit ratio of hemodialysis in acute barbiturate overdose, it remains a legitimate option for severe phenobarbital toxicity. Because phenobarbital is 40% to 60% protein bound, in the past hemoperfusion was advocated over hemodialysis; however, newer

- Butalbital (Fiorinal)

**LONG ACTING**
- Phenobarbital (Solfoton, Luminal)
- Mephobarbital (Mebaral)
high-efficiency dialyzers using high blood flow rates provide drug clearance greater than that achieved by hemoperfusion. Although rarely indicated, we recommend hemodialysis for acute pheno-barbital toxicity (serum levels over 100 mcg/mL) in the presence of refractory hypotension, renal or cardiac failure, acid-base or electrolyte abnormalities, or inadequate response to less invasive measures (as assessed by declining serum levels).

Disposition
An asymptomatic patient who arrives in the emergency department (ED) after ingesting barbiturates should be observed for 6 hours after ingestion for mental status changes, slurred speech, ataxia, hypotension, and respiratory depression. Symptoms generally occur within 1 hour of ingestion. Patients who remain asymptomatic and have no significant complicating co-ingestants or medical problems can be discharged or referred for psychiatric care. Patients who are still symptomatic after 6 hours should be admitted to a monitored setting for observation and supportive care. Those with refractory hypotension, prolonged coma requiring intubation and ventilator support meet intensive care unit criteria for admission.

BENZODIAZEPINES
With the development of chlordiazepoxide in 1960 and diazepam in 1963, benzodiazepines, with their vastly superior safety profile, rapidly supplanted barbiturates and other non-barbiturate sedative-hypnotics as the principal agents for the treatment of anxiety and insomnia. Benzodiazepines remain among the most widely prescribed class of drugs (Table 159.1) and are the most common prescription drugs used in suicide attempts. Pediatric patients comprise 10% of benzodiazepine overdose cases.

Principles of Toxicity
Most benzodiazepine overdoses follow a relatively benign clinical course. Benzodiazepines produce sedative, hypnotic, anxiolytic, and anticonvulsant effects by enhancing the inhibitory actions of GABA. Binding of a benzodiazepine to a specific benzodiazepine receptor potentiates GABA effects on the chloride channel at the GABA<sub>A</sub> receptor, increasing intracellular flux of chloride ions and hyperpolarizing the cell. The net effect is a diminished ability of the nerve cell to initiate an action potential, inhibiting neural transmission.

Three unique benzodiazepine receptors exist, distributed variably throughout the central and peripheral nervous systems. Classic benzodiazepines are nonselective, producing a broad range of clinical effects. Newer benzodiazepines interact selectively with a single receptor subtype to achieve a desired result, such as sedation, while minimizing unwanted effects.

Pharmacokinetics
Benzodiazepines are rapidly absorbed orally. Intramuscular use of chlordiazepoxide and diazepam is limited by erratic absorption, but lorazepam and midazolam are predictably absorbed after intramuscular injection. After absorption, benzodiazepines distribute readily and rapidly penetrate the blood-brain barrier. In plasma, benzodiazepines are highly protein bound.

All benzodiazepines are metabolized in the liver. Oxazepam, temazepam, and lorazepam are directly conjugated to an inactive, water-soluble glucuronide metabolite that is excreted by the kidney. Other benzodiazepines must first be converted by the hepatic cytochrome P<sub>450</sub> system. Chlordiazepoxide, diazepam, flurazepam, and clorazepate are metabolized to active derivatives that are then slowly conjugated and excreted. The long elimination half-lives of these intermediates can cause accumulation in the body with repeated dosing. Triazolam, alprazolam, and midazolam are converted to hydroxylated intermediates that are active but rapidly conjugated and excreted and do not contribute significantly to the drug’s overall effect.

Cytochrome P<sub>450</sub> processes may be significantly impaired in elderly patients or those with liver disease, leading to prolonged elimination of some benzodiazepines. Co-ingestion of drugs that also undergo cytochrome P<sub>450</sub> metabolism (eg, cimetidine, ethanol) prolongs the half-lives of these benzodiazepines.

</table>
Clinical Features

CNS depression, which is common in patients with benzodiazepine poisoning, ranges from mild drowsiness to coma. Cardiac effects and fatalities from pure benzodiazepine overdose are rare. Respiratory depression, although less severe than with barbiturates, is the most important clinical effect requiring intervention.5 Upper airway obstruction and increased upper airway resistance from loss of muscle tone, rather than central apnea, are the main causes of respiratory compromise. Life-threatening respiratory depression is rare but can be seen with large oral overdoses or during intravenous procedural sedation, particularly when the benzodiazepine is combined with an opioid, such as fentanyl. Hypotension is uncommon. Other potential complications include aspiration pneumonia and pressure necrosis of skin and muscles.

Most children have symptoms within 4 hours of benzodiazepine ingestion. Ataxia is the most common sign of toxicity, occurring in 90% of pediatric patients. Respiratory depression occurs in fewer than 10% of pediatric cases, and hypotension has not been reported in children.

Prolonged or high-dose infusions of certain benzodiazepine preparations have been associated with the development of lactic acidosis. Intravenous solutions of diazepam and lorazepam contain propylene glycol, which is metabolized to lactate. Patients with renal or hepatic insufficiency are at increased risk for this complication.1

Differential Diagnoses

Benzodiazepine overdose is usually suspected or diagnosed by clinical presentation. Many patients are arousable and can provide supporting information. Atypical or focal findings suggest the presence of other conditions, such as intracranial events (eg, cerebral vascular accident [CVA], intracerebral hemorrhage). Profound coma or cardiopulmonary instability is rare with pure benzodiazepine overdose and should prompt the search for co-ingestants, such as phenobarbital, a cyclic antidepressant, or chloral hydrate. Non-toxicologic metabolic causes of CNS depression (such as, hypoglycemia) and endocrine issues (such as, hypothyroidism) should also be considered.

Diagnostic Testing

Any patient with altered mental status should have a blood glucose level rapidly determined. Qualitative immunoassays for benzodiazepines in urine are available, but do not aid management decisions. Because most of these screening tests detect only benzodiazepines that are metabolized to oxazepam glucuronide, some benzodiazepines (such as, clonazepam, lorazepam, midazolam, and alprazolam), will not show up on many urine drug tests. A positive urine drug screen for benzodiazepines indicates recent exposure but does not confirm intoxication or indicate a specific agent. Serum drug concentrations are not routinely available and do not correlate with clinical severity. A lack of alcohol odor or a negative breathalyzer or blood ethanol test result suggests benzodiazepine or another sedative as a possible cause.

The benzodiazepine antagonist flumazenil should not be routinely administered to patients with coma of unknown origin or suspected benzodiazepine overdose, for diagnostic purposes.89

Management

General

Initial stabilization, including endotracheal intubation, should not be delayed by the administration of an antidote. Most benzodiazepine overdoses can be managed expectantly with supportive care alone. Single dose or multidose activated charcoal, hemodialysis, and whole bowel irrigation are not effective in benzodiazepine overdose and therefore are not indicated.

Antidote

Flumazenil, a nonspecific competitive antagonist at the benzodiazepine receptor, can reverse benzodiazepine-induced sedation after general anesthesia, procedural sedation, and confirmed benzodiazepine overdose. However, when compared to placebo, the risks of flumazenil usually out-weigh the benefits in patients with toxicity, and flumazenil is not recommended for the routine reversal of sedative overdose in the ED.90 Although theoretic benefits of flumazenil use include cost savings and avoidance of procedures and tests (such as, endotracheal intubation and lumbar puncture), several studies have not been able to demonstrate an actual benefit.90 Seizures and cardiac dysrhythmias (principally paroxysmal supraventricular tachycardia [PSVT]) can occur after flumazenil administration, and fatalities have been reported. Flumazenil use can also precipitate acute withdrawal in patients who are chronically dependent on benzodiazepines. Similarly, this antidote is hazardous when it is given to patients who have co-ingested seizure-generating drugs (such as, cocaine, isoniazid, or a tricyclic antidepressant) because of loss of the benzodiazepine’s protective anti-convulsant properties. Co-ingestants that cause dysrhythmias, such as carbamazepine and chloral hydrate, may increase the likelihood of cardiac effects. Other risk factors are summarized in Box 159.2. When nonbenzodiazepine-dependent patients ingest benzodiazepines alone in overdose (as might be expected in children), the risks associated with flumazenil are low.9 In cases of benzodiazepine overdose by a non-benzodiazepine habituated patient, flumazenil use, combined with close monitoring and repeated or infusion-based dosing, may obviate the need for intubation and mechanical ventilation. We recommend basing this decision on a balance of risks/benefits for the particular patient and the reliability of the assessment that the patient is a novice benzodiazepine user.

BOX 159.2

Use of Flumazenil

INDICATIONS
Isolated benzodiazepine overdose in non-habituated user (eg, accidental pediatric exposure)
Reversal of conscious sedation

ABSOLUTE CONTRAINDICATIONS
Suspected co-ingestant that lowers seizure threshold (eg, tricyclic antidepressants, cocaine, lithium, methylxanthines, isoniazid, propoxyphene, monoamine oxidase inhibitors, bupropion, diphenhydramine, carbamazepine, cyclosporine, chloral hydrate)
Patient taking benzodiazepine for control of a potentially life-threatening condition (eg, seizures)
Concurrent sedative-hypnotic withdrawal
Seizure activity or myoclonus
Hypersensitivity to flumazenil or benzodiazepines
Patient with neuromuscular blockade

RELATIVE CONTRAINDICATIONS
Chronic benzodiazepine use, not taken for control of life-threatening condition
Known seizure disorder not treated with benzodiazepines
Head injury
Panic attacks
Chronic alcoholism
The initial adult dose of flumazenil is 0.2 mg given intravenously over 30 seconds. A second dose of 0.2 mg may be given, followed by 0.2-mg doses at 1-minute intervals to a total of 1 mg. In children, the initial dose is 0.01 mg/kg (up to 0.2 mg). Because the duration of action of flumazenil is short (0.7 to 1.3 hours), re-sedation occurs in up to 65% of patients and requires either re-dosing or continuous infusion (0.25 to 1.0 mg/hr).

In summary, benzodiazepine overdose requires primarily supportive care (including, in some cases, intubation). Flumazenil may precipitate seizures or acute withdrawal and should be used only in highly selected cases (eg, to reverse procedural sedation, or to treat children with a clear history of inadvertent benzodiazepine ingestion). When flumazenil is used, close monitoring of oxygen-hemoglobin saturation and overall status (ideally including end-tidal CO₂) is necessary because of the risk for recurrent respiratory depression or re-sedation. Use of flumazenil has not been shown to alter outcome, complication rate, number of costly procedures performed, or duration of hospital stay in patients presenting to the ED with benzodiazepine overdose.

**Disposition**

Patients remaining asymptomatic after 4 to 6 hours of ED observation may be medically cleared. For cases of deliberate overdose, appropriate psychiatric consultation should be obtained. Patients presenting with respiratory depression and coma should be given oxygen, ventilatory support, and admission to a monitored setting.

**Benzodiazepine Withdrawal Syndrome**

Abrupt discontinuation of a benzodiazepine in a chronic user results in a characteristic constellation of symptoms similar to ethanol withdrawal (Box 159.3). Risk for withdrawal is a function of both the dose of benzodiazepine and the duration of its use. Continuous treatment for more than 4 months is generally required before a patient is at risk for withdrawal. With abrupt discontinuation of a benzodiazepine, the most severe withdrawal symptoms are expected within several days to a week. Treatment of withdrawal consists of restarting benzodiazepines.

**SPECIAL CONSIDERATIONS**

**Flunitrazepam**

Flunitrazepam (Rohypnol) has been used in Europe, Asia, and Latin America for insomnia and preoperative sedation since 1975. Although it has never been manufactured or sold in the United States, flunitrazepam has been documented in many sexual assault or “date rape” incidents. Flunitrazepam has been an active agent in the illicit drug market, where it is used to alter the effects of other drugs, including ethanol, heroin, and cocaine. Flunitrazepam has 10 times more affinity than diazepam for certain benzodiazepine receptors. CNS depression occurs within 30 minutes. The drug is most frequently ingested with alcohol, producing additional disinhibition and amnesia. Despite marked CNS depression, patients can usually be aroused with noxious stimuli. The half-life of the drug is 16 to 35 hours, but coma can be prolonged for up to 48 hours. Flunitrazepam is easily obtained outside the United States and on the Internet. The drug is not detected on routine urine drug screens, but if needed as evidence, a urine sample should be refrigerated or frozen and the local or state police crime laboratory contacted to arrange specific testing. Metabolites of flunitrazepam are detected in the urine up to 72 hours after exposure.

**Buspirone**

Buspirone (BuSpar) has been used for generalized anxiety since the 1980s. Unlike benzodiazepines, buspirone does not have any effect on GABA. It is, rather, a partial serotonin (5-hydroxytryptamine type 1A [5-HT₁A]) agonist. To a lesser extent, it also antagonizes dopamine (D₂) receptors. Buspirone has no hypnotic, anticonvulsant, or muscle relaxant effects. Buspirone has several advantages over benzodiazepines. The drug causes minimal CNS depression, even in combination with ethanol. Dosage adjustment is not needed for elderly patients. A withdrawal state after discontinuation has not been reported.

**Zolpidem, Zaleplon, and Zopiclone**

Zolpidem (Ambien), zaleplon (Sonata), and zopiclone (Imovane) differ in structure from both the benzodiazepines and buspirone, and they are not detected on a benzodiazepine toxicology screen. They act selectively at a specific benzodiazepine receptor, producing sedation without many of the side effects seen with benzodiazepines. They have modest anxiolytic, muscle relaxant, and anticonvulsant properties. Significant drug interactions are rare. Compared with zolpidem, zaleplon causes less memory loss and sedation at therapeutic doses and is more rapidly eliminated. Of the three “Z-drugs,” zopiclone has the longest duration of action. Transient visual disturbances, transient global amnesia, hallucinations, and somnambulism can occur in patients with normal levels of consciousness with both zolpidem and zaleplon. Abuse of zolpidem is limited by vomiting, which may occur after a supratherapeutic dose. Both zolpidem and zaleplon are rapidly eliminated and lack active metabolites. A controlled-release formulation of zolpidem (Ambien CR) is also available. The dual-layered tablet releases an immediate dose of zolpidem, followed by a slow, extended release from the inner layer to maintain plasma zolpidem concentrations. Clinical experience thus far suggests that overdoses with the controlled-release formulation mirror those of the immediate-release preparation, with only small differences in the likelihood of drowsiness, hallucinations, and ataxia.

Patients with zolpidem overdose do well with supportive care alone. Fatalities from isolated zolpidem overdose are rare. All published cases have involved individuals found dead at home and have been associated with co-ingestants, particularly other sedative-hypnotics or antipsychotics. Drowsiness is by far the most common symptom. Coma and respiratory failure are rare, despite overdoses of up to 40 times the normal dose, although intubation may be required, particularly if there are co-ingestants. Zolpidem overdose in children generally follows a similarly benign course. Drowsiness, ataxia, and hallucinations generally resolve within 8 to 10 hours.

Overdose information for zaleplon is limited. Patients generally experience CNS depression and mild hypotension. Arousal can be temporally associated with flumazenil administration, but routine use is not advised. Adverse effects with therapeutic use include headache, anterograde amnesia, and transient visual hallucinations. The blue-green discoloration of gastric contents, mouth, and urine after zaleplon overdose is attributed to the indigo carmine dye present in zaleplon’s capsule shell.

---

**BOX 159.3**

**Benzodiazepine Withdrawal Symptoms**

**NONSPECIFIC**
Anxiety, depression, insomnia, tremor, tachycardia, sweating

**SEVERE (RARE)**
Visual hallucinations, delirium, seizures
Eszopiclone

Eszopiclone (Lunesta) has been marketed in the United States for treatment of insomnia. It is the S-isomer of racemic zopiclone, which has been used for decades outside the United States. Eszopiclone has a structure unrelated to that of benzodiazepines or barbiturates.

The mechanism of eszopiclone’s action involves a specific GABA<sub>R</sub> receptor close to or coupled with the benzodiazepine receptor. Eszopiclone is rapidly absorbed, with a peak serum level at 1 hour and a half-life of 6 hours. It is metabolized in the liver to minimally active metabolites. The usual bedtime dose is 3 mg. It is recommended that elderly patients and those with hepatic insufficiency be treated with a lower (1 mg) dose.

Adverse effects with therapeutic use of eszopiclone include drowsiness, dizziness, dry mouth, unpleasant taste, nausea, and vomiting. Auditory and visual hallucinations have been reported. Experience with eszopiclone overdose is limited. The key to treatment is supportive care. CNS depression may be prolonged and pronounced in elderly patients. A retrospective case review described over 500 eszopiclone ingestions; however, half of these patients had also ingested other drugs or chemicals. The ingestions involved eszopiclone doses up to 200 mg and had mild to moderate symptoms at most. Two deaths occurred, both involving significant co-ingestants.

CHLORAL HYDRATE

Principles of Toxicity

Chloral hydrate has a low therapeutic ratio and can produce significant, potentially fatal toxicity. Chloral hydrate is rarely used today but is still occasionally prescribed as a sedative in the elderly and for children undergoing hospital and outpatient procedures. The hypnotic oral adult dose is 0.5 to 1.0 g. The toxic oral dose is approximately 10 g in adults and may be as little as 1.5 g in children.

The toxic effects of chloral hydrate include CNS depression, gastrointestinal irritation, cardiovascular instability, hepatitis, and proteinuria. The primary active metabolite of chloral hydrate, trichloroethanol, has a barbiturate-like effect on GABA<sub>R</sub> receptors and is responsible for most of the CNS depression seen with significant overdose.

Chloral hydrate is rapidly absorbed from the gastrointestinal tract and almost immediately metabolized to trichloroethanol by the enzyme alcohol dehydrogenase. Onset of action is 20 to 30 minutes. Trichloroethanol is long acting, and its half-life can be significantly prolonged after overdose as metabolic pathways become saturated.

Chloral hydrate and ethanol in combination (historically referred to as a “Mickey Finn”) potentiate each other’s action to produce rapid loss of consciousness. Chloral hydrate increases the half-life of ethanol by competitively inhibiting the enzyme alcohol dehydrogenase, and the metabolism of ethanol generates nicotinamide adenine dinucleotide (NADH), a cofactor for the conversion of chloral hydrate to trichloroethanol.

Clinical Features

Chloral hydrate toxicity causes CNS and respiratory depression, gastrointestinal irritation, cardiovascular instability, and dysrhythmias. The combination of deep coma and cardiac dysrhythmia without hypoxia is characteristic of severe cases.

A pear-like odor to the patient’s breath or gastric contents may suggest the diagnosis. Findings consistent with chloral hydrate toxicity include miosis, muscle flaccidity, diminished deep tendon reflexes, hypoventilation, hypotension, and hypothermia. Chloral hydrate is corrosive and causes nausea, vomiting, esophagitis, hemorrhagic gastritis, and, rarely, gastrointestinal perforation or necrosis. Transient hepatic or renal dysfunction can also occur.

Dysrhythmias from chloral hydrate toxicity can be fatal. Chloral hydrate decreases myocardial contractility, shortens the cardiac refractory period, and increases the sensitivity of myocardium to catecholamines. Dysrhythmias include atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, multifocal premature ventricular contractions, torsades de pointes, ventricular fibrillation, and asystole. Hypotension results from inhibition of central neurovascular regulatory centers and impaired myocardial contractility.

Differential Diagnoses

Mild chloral hydrate toxicity can mimic the effects of ethanol, benzodiazepines or barbiturates, with drowsiness, ataxia, and lethargy. Other agents to consider in the differential diagnosis of chloral hydrate toxicity include the anesthetic drugs ketamine, propofol, and etomidate. More severe toxicity mimics other cardiotoxic drugs, including tricyclic antidepressants, diphenhydramine, and cocaine. Torsades de pointes may suggest acute quinine or arsenic poisoning, as well as hypomagnesemia.

Management

The key to management is support of cardiorespiratory function. Intubation may be required for airway protection or to support ventilation and oxygenation. Avoid naloxone or flumazenil, which may precipitate ventricular dysrhythmias. Because chloral hydrate, like other chlorinated hydrocarbons, sensitizes myocardium to catecholamines, epinephrine and norepinephrine should also be avoided. Standard antidysrhythmic agents, such as lidocaine, do not appear effective against chloral hydrate-induced cardiac ectopy. The treatment of choice for chloral hydrate-induced dysrhythmias is a beta-blocker. Intravenous propranolol can be given in adult doses of 0.5 mg until ectopy is suppressed, followed by an infusion of 1 to 2 mg/hr, titrated to a heart rate of 80 to 100 beats/minute. A short-acting agent, such as esmolol, can also be used. Torsades de pointes should be treated with intravenous magnesium or overdose pacing, as described in Chapter 69. Type I antidysrhythmic agents, such as quinidine, should be avoided. Unstable patients not responding to conservative therapy can be treated with hemoperfusion or hemodialysis.

Disposition

Patients with acute chloral hydrate overdose, whether accidental, intentional or iatrogenic, should be observed in the ED until clinically stable, alert, oriented, and ambulatory. In cases of prolonged altered mental status, respiratory depression, hypoxia, or evidence of cardiotoxicity (ie, PSVT, QRS widening, QTc prolongation, torsades de pointes), the patient should be admitted to a monitored setting. If the intent of the overdose was self-harm, psychiatric consultation is indicated once the patient is medically stabilized.

OVER-THE-COUNTER SLEEP AIDS

Over-the-counter (OTC) sleep aids currently available in the United States contain either diphenhydramine or doxylamine. Many preparations also contain acetaminophen or aspirin, added to achieve nighttime pain relief. The availability and frequent use of these agents may explain why overdose is so common.
**Principles of Toxicity**

Diphenhydramine and doxylamine are antihistamines that also have hypnotic, antimuscarinic, and weak local anesthetic properties. They act as competitive antagonists of H1 histamine receptors and cause sedation by inhibiting the actions of acetylcholine on muscarinic receptors in the CNS. Their toxicity is described in Chapter 145.

**GAMMA-HYDROXYBUTYRATE**

Originally synthesized in the 1960s as an anesthetic, GHB was later discovered to be a naturally occurring metabolite of GABA. Since 1970, GHB has been used to treat narcolepsy, alcohol addiction, opioid withdrawal, and depression.1,3,4 The sale and manufacture of GHB were banned in 1990; however, illicit use of GHB increased, along with its precursors gamma-butyrolactone (GBL) and 1,4-butane diol (1,4-BD). There is a wide variety of “street names” that have been associated with GHB (Box 159.4). The FDA approved GHB for the treatment of narcolepsy under the trade name Xyrem (sodium oxybate, 0.5 mg/mL) as a schedule III drug in 2005.

GHB remains a popular drug of abuse. Some individuals take GHB for its purported muscle-building and fat-burning actions, others for its psychoactive effects. The drug’s euphoria-producing properties make it popular at “raves” (large, crowded youth parties with energetic dancing to rhythmic music for many hours). Self-treatment of insomnia with GHB has been reported and can cause dependence. CNS depression, amnesia, and disinhibitions caused by mixing of GHB with ethanol make this combination a potential agent in “date rape” situations. After overdose, a call for medical assistance is often delayed because of the false belief that victims need only “sleep off” their intoxications. Death occurs most often in the prehospital setting, both from direct effects of the drug and increased the risk for fatal accidents. Combined intoxication with ethanol occurs in 40% of fatal cases, but GHB is the sole intoxicant in one-third of deaths, underlining the lethal potential of the drug and its congeners.1,5,6 Other common co-ingestants include amphetamines, cocaine and ketamine. Chemical precursors to GHB are also commonly abused. GBL is rapidly converted to GHB by aldehyde dehydrogenase. Like GBL, it is used as an industrial solvent. Unlike GBL, 1,4-BD itself has sedative-hypnotic effects. Clinical findings are similar to those of GHB. When 1,4-BD and ethanol are ingested together, ethanol acts as a competitive inhibitor of alcohol dehydrogenase, so the toxic effects of 1,4-BD are delayed and prolonged, and the risk of death is increased. 1,4-BD is available under a number of street names (Box 159.5).

1,4-BD is converted after ingestion to GHB by the enzyme alcohol dehydrogenase. Like GBL, it is used as an industrial solvent. Unlike GBL, 1,4-BD itself has sedative-hypnotic effects. Clinical findings are similar to those of GHB. When 1,4-BD and ethanol are ingested together, ethanol acts as a competitive inhibitor of alcohol dehydrogenase, so the toxic effects of 1,4-BD are delayed and prolonged, and the risk of death is increased. 1,4-BD is available under a number of street names (Box 159.6).

**Clinical Features**

Diagnosis of GHB intoxication is based on the history and clinical course. Rapid recovery from coma, or periods of agitation alternating with periods of decreased level of consciousness, is characteristic. Hypothermia may occur with prolonged coma. In the presence of coma, bradycardia with or without hypotension can occur and may respond to stimulation alone. Miosis with or without nystagmus may be seen. Because emesis occurs in about 50% of cases, obtunded patients are at risk for aspiration pneumonia. Apparent seizure activity may actually represent random myoclonic movements of the face and extremities. Severity is dependent on the dose and the concurrent use of alcohol or other psychoactive drugs.

Differential Diagnoses
The differential diagnoses of GHB intoxication is broad including other sedative hypnotics (such as, barbiturates or benzodiazepines), OTC sleep aids, antimuscarinic agents, opioids, ethanol, ketamine, chloral hydrate, and designer amphetamines.
Poisoning with other sedative-hypnotics can produce a similar clinical picture. Unique to GHB, however, is the relatively rapid resolution of symptoms. In the absence of a co-ingestant such as ethanol, most patients will be functionally awake within 3 to 4 hours. Nearly all patients recover fully within 8 hours. Prolonged coma should prompt a search for another toxicological or non-toxicological cause. Cardiac effects and refractory seizures are rare and suggest the presence of other agents or etiologies.

Diagnostic Testing
GHB is not detected on routine urine toxicology screens. If laboratory confirmation is required, specimens must be collected early and sent for gas chromatography–mass spectroscopy. The drug may be detected in urine up to 12 hours after ingestion.

Management
Because of the high incidence of emesis with GHB overdose, there is no indication for gastric decontamination. Intubation for airway protection may be required for patients with significant CNS depression or hypoxia. Treatment of isolated GHB ingestion is supportive. Although some authors suggest administering physostigmine to reverse GHB-induced coma, the efficacy and safety of this intervention have not been demonstrated, and physostigmine is not indicated or recommended.

Withdrawal
Patients who suddenly stop GHB or its precursors after chronic, frequent use can experience a severe and potentially life-threatening withdrawal syndrome.4 Because of the short half-life of GHB, symptoms of withdrawal begin within several hours of the last dose. The typical patient will have been using these products for weeks or years, every 1 to 3 hours around-the-clock, to avoid withdrawal symptoms.
Mild withdrawal is manifested with anxiety, tremor, and insomnia. This can progress to confusion, delirium, overt psychosis, paranoid ideation, hallucinations (visual, aural, or tactile), and autonomic instability. Diagnosis relies on a history of symptoms beginning after abrupt cessation of use of these products. The differential diagnosis includes withdrawal from other sedative hypnotic agents, delirium tremens, sympathomimetic toxicity, serotonin syndrome, neuroleptic malignant syndrome, CNS infection, and thyroid storm.
Initial treatment begins with high-dose benzodiazepines (lorazepam 1 to 2 mg intravenous push [IVP] every 30 to 60 minutes as required for agitation). However, GHB withdrawal may involve depleted levels of GABA. Because the effect of benzodiazepines requires the presence of GABA, they may not be effective in control of GHB withdrawal. Barbiturates, such as pentobarbital or phenobarbital, which do not need GABA to be effective, are often required in cases of severe withdrawal. These patients often require admission to an intensive care unit for titrated sedation, as well as to monitor vital signs and observe development of rhabdomyolysis or hyperthermia.

Disposition
Because of GHB’s short half-life, symptoms generally resolve while the patient is still in the ED. The patient generally regains consciousness spontaneously within 3 to 4 hours. No delayed toxicity is expected unless co-ingestants have been taken. Patients should be counseled about the seriousness of GHB intoxication, withdrawal potential with chronic use, and discharged home with reliable caretakers.

KEY CONCEPTS
• Barbiturate intoxication is rare, and most patients recover with observation and supportive care alone. Hemodialysis is not indicated unless the patient remains hemodynamically unstable despite adequate supportive measures.
• A urine toxicology screen positive for barbiturates does not prove that the drug caused the patient’s clinical condition. Serum barbiturate levels confirm the diagnosis, but do not correlate well with depth of coma or clinical outcome.
• Flumazenil is not indicated in the majority of benzodiazepine overdoses, particularly not in regular benzodiazepine users, in whom flumazenil can precipitate seizures. Because flumazenil’s duration of action (about 1 hour) is much shorter than that of all commonly available benzodiazepines, if flumazenil is used patients should be monitored closely for recurrent respiratory depression or re-sedation.
• Chloral hydrate toxicity may result in sedation and cardiotoxicity, principally in the form of supraventricular tachycardias, which are best treated with a beta blocker.
• Endotracheal intubation to protect against emesis, aspiration pneumonitis, and hypoxia is often necessary for patients with significant CNS or respiratory depression from GHB overdose.
• Withdrawal from GHB or its precursors begins with anxiety, tremor, and insomnia, but it can progress to a severe syndrome characterized by delirium and autonomic instability. Management of this syndrome often requires high-dose benzodiazepine or barbiturate therapy.

159.1. How do barbiturates affect peripheral and cerebral blood flow?

A. Decrease peripheral pressure and have no effect on intracranial pressure
B. Decrease peripheral pressure and increase intracranial pressure
C. Decrease peripheral and intracranial pressure
D. Increase peripheral and intracranial pressure
E. Increase peripheral pressure and decrease intracranial pressure

**Answer:** C. Barbiturates cause direct cardiac depression with decreased cardiac output. In addition, they cause venous pooling and blunt the normal compensatory increase in systemic vascular resistance that would occur with decreased cardiac output. They also decrease cerebral blood flow and lower intracranial pressure. These effects are particularly pronounced in individuals with an already low cardiac output, such as in congestive heart failure or hypovolemic shock.

159.2. Other than general supportive care, which of the following is most useful in the management of a severe phenobarbital overdose with hemodynamic instability?

A. Flumazenil
B. Hemodialysis
C. Multidose activated charcoal
D. Urinary alkalization
E. Whole bowel irrigation

**Answer:** B. Although rarely indicated, hemodialysis is effective for acute phenobarbital toxicity (serum levels over 100 mcg/mL) in the presence of refractory hypotension, renal or cardiac failure, acid-base or electrolyte abnormalities, or inadequate response to less invasive measures (as assessed by declining serum levels). These patients often require mechanical ventilation, so the patient’s airway should be secured prior. Although there is evidence that multi-dose activated charcoal (MDAC) increases clearance of phenobarbital and may shorten duration of clinical toxicity, there is no evidence it results in improved outcomes over supportive care alone. Flumazenil will reverse the effect of barbiturates but has no effect on barbiturates. Urinary alkalization has traditionally been used to "trap" the acidic barbiturates in the urine to increase excretion. However, a recent comprehensive review concluded that there is little clinical role for urine alkalization in acute barbiturate poisoning. Whole bowel irrigation is not beneficial.

159.3. All of the following patients have depressed mental status, decreased respiratory drive, and mild hypotension. Supportive care has been initiated. All of the patients have a confirmed benzodiazepine overdose by a reliable historian. For which patient is it most reasonable to consider the use of flumazenil?

A. A 5-year-old boy with no known medical problems who took his mother’s medication
B. A 22-year-old woman with no known medical problems
C. A 30-year-old man who is known to abuse cocaine
D. A 43-year-old man with depression and anxiety
E. A 79-year-old woman with congestive heart failure, coronary artery disease, and diabetes who takes benzodiazepines for insomnia

**Answer:** A. Flumazenil variably reverses the effects of benzodiazepines but can cause dysrhythmias and intractable seizures. Contraindications for flumazenil include history or suspected chronic benzodiazepine use (which are the vast majority of benzodiazepine overdose patients), co-ingestants that lower the seizure threshold, tricyclic antidepressants, cocaine, history of seizure disorder, chronic alcoholism, and head trauma. Its use should be for a known non-habituated patient (eg, the pediatric patient described here). Because flumazenil’s duration of action is short compared with the benzodiazepine and it has variability to reverse respiratory depression, patients require close, monitored observation, repeated dosing or continuous infusion, and preparations to manage the airway. Because benzodiazepine overdose is rarely lethal and patients recover with supportive care, using an antidote requires a careful benefit/risk analysis.

159.4. Which of the following sedative hypnotics is most likely to cause fatal cardiac dysrhythmias in overdose?

A. Buspirone
B. Chlordiazepoxide
C. Eszopiclone
D. Flunitrazepam
E. Zolpidem

**Answer:** B. Chlordiazepoxide is a short-acting benzodiazepine with a rapid onset of action. It can cause severe hypotension and bradycardia, which may lead to cardiac arrest. The other options are less likely to cause fatal cardiac dysrhythmias in overdose.
159.5. A 53-year-old woman presents with decreased mental status and mild hypotension. She is arousable to pain. Her husband reports that approximately 4 hours ago she had been complaining of insomnia and said she was going to take something to help her sleep. He then found her in her present state with an empty bottle of “sleeping pills” on the counter. He does not remember the name of the sleeping pills. Supportive care is initiated. Which of the following laboratory tests would be the most helpful to manage this patient?
A. Acetaminophen level
B. Arterial blood gas
C. Serum chemistry
D. Serum myoglobin
E. Urine drug screen

**Answer:** A. Many over-the-counter (OTC) sleep aids contain acetaminophen or salicylates. The active ingredient in OTC sleep aids is an antihistamine, typically diphenhydramine or doxylamine. Both have anticholinergic effects in addition to causing sedation. Toxicity is typically mild and can be successfully managed with supportive care. It is rare that an antihistamine overdose results in rhabdomyolysis, and a serum creatine phosphokinase level, urinalysis, and urinary myoglobin level can be checked if there is concern. Myoglobin is cleared rapidly from the serum and is not a useful diagnostic test. Arterial blood gases, serum chemistries, and urine drug screens can be ordered if there is a complicated clinical course—but only rarely alter treatment.

159.6. A 21-year-old woman is brought to the emergency department (ED) by her friends after they found her unconscious in the bathroom of a local bar. The friends report that she had only had one or two alcoholic drinks. The patient’s vital signs show mild bradycardia, hypotension, and bradypnea. Physical examination reveals miosis and short periods of apnea. She wakens briefly to noxious stimuli. You suspect that she may be suffering from gamma-hydroxybutyrate (GHB) poisoning. What is the most appropriate next step in management?
A. Atropine
B. Electrocardiogram
C. Endotracheal intubation
D. Flumazenil
E. Naloxone

**Answer:** C. GHB frequently causes emesis and aspiration because patients are unable to protect their airways. Patients with significant GHB overdose should be intubated, but supportive care alone is all that is required for most GHB overdoses. The half-life is short, and many patients will return to baseline mental status in several hours. Bradycardia is common, usually mild, and does not typically require atropine, but this can be used if bradycardia is severe. GHB does not cause dysrhythmias. Neither flumazenil nor naloxone has any effect on GHB.

159.7. A 30-year-old man presents with anxiety and insomnia. He is agitated and has a tremor on physical examination. His vital signs are as follows: blood pressure, 200/124 mm Hg; heart rate, 123 beats/min; respiratory rate, 22 breaths per minute; and temperature, 37.5° C. On further questioning, he reports that he chronically uses gamma-hydroxybutyrate (GHB) for muscle building but has not been able to take any for approximately 24 hours. Lorazepam is given in two escalating doses without response. Which of the following should be given next?
A. A barbiturate
B. Additional lorazepam
C. Clonidine
D. GHB
E. Labetalol

**Answer:** A. GHB withdrawal is severe, and deaths have been reported. GHB acts as a central nervous system (CNS) depressant, so withdrawal causes CNS excitement and autonomic instability. Chronic GHB abuse can lead to GABA depletion in the CNS. Because benzodiazepines require the presence of GABA, they may not be effective. Barbiturates act independently of GABA and are therefore more effective in GHB withdrawal. Clonidine can be used in opioid withdrawal but is not useful in GHB withdrawal. Labetalol would improve the vital signs but would have no effect on the underlying cause of the autonomic instability.

**General Approach to the Pediatric Patient**

*Margaret G. Huang | Genevieve Santillanes*

### PRINCIPLES

Emergency clinicians assess and manage pediatric patients from newborns to adolescents. Of the 136 million annual US emergency department (ED) visits, 25 million (18%) are for children younger than 15 years. 2 Twenty-two percent of children have at least one ED visit per year. 2 Infants have higher per capita ED utilization than other age groups, with 873 visits/100 infants. 1 More than 80% of pediatric patients are seen in general EDs, requiring all emergency clinicians to be skilled in the assessment, treatment, and stabilization of pediatric illnesses and injuries. 3, 4

Children can present diagnostic and management challenges due to their anatomic, physiologic, and developmental differences from adult patients. Understanding these differences is crucial to the recognition and appropriate treatment of many pediatric emergencies. In addition, caring for the pediatric patient also involves active participation from caregivers.

### Pathophysiology

Children exhibit different patterns of illness and injury because of their unique physiologic and anatomic characteristics. Illness and injury patterns not only differ between pediatric and adult patients, but also vary in children by age. In addition to changes in cognitive and behavioral development, temperature regulation, airway anatomy, cardiovascular physiology, immune function, and the musculoskeletal system all change as children grow. Furthermore, pediatric patients may present to the ED with previously undiagnosed congenital disorders. Drug dosing and choice of medications also depend on patient size and physiology.

Assessment should begin with a review of vital signs, evaluating for early signs of physiologic decompensation. Normal heart rate and respiratory rate vary by age (Table 160.1). Normal blood pressure also varies by age, height, and gender (Box 160.1; Table 160.2). Abnormal vital signs should be repeated and persistently abnormal vital signs quickly addressed.

### Temperature Regulation

Infants and young children have a larger surface area-to–mass ratio, resulting in more heat loss to the environment than in adolescents and adults. Maintenance of a stable body temperature can be a significant metabolic demand for young infants, especially those stressed by injury or illness. Maintain a neutral thermal environment for children during the physical examination and while performing procedures. Patients exposed briefly for examinations and interventions should be covered as soon as possible to avoid excessive heat loss. Critically ill young infants should be placed under radiant warmers. Overhead warming lights are useful for older infants and children who require prolonged exposure for resuscitation and procedures.

### Airway

The pediatric airway differs in a number of ways from an adult airway. 5, 6 Compared to the adult airway, the pediatric larynx is more anterior and cephalad, and the epiglottis is composed of more flexible cartilage, making it floppy. The relatively larger occiput in infants and young children can cause neck flexion in the supine position, leading to potential airway obstruction. To open the airway, particularly during intubation attempts, a towel roll placed under the shoulders may be needed to align the laryngeal, pharyngeal, and oral airway axes (Fig. 160.1). Infants and young children also have relatively large tongues, which may lead to airway obstruction during periods of changes in muscle tone, such as during a seizure. Use of a nasopharyngeal airway can alleviate the obstruction by allowing a clear passage of inhaled gases. In addition, airways in children are much smaller in diameter and much more easily obstructed with secretions. Because young infants preferentially breathe through their noses, respiratory distress can develop from copious nasal secretions. Thus, suctioning the nose and upper airway can dramatically diminish an infant’s work of breathing.

### Cardiovascular System

Healthy children have compensatory mechanisms to maintain blood pressure, even when cardiac output is decreasing. Children have the ability to increase their heart rate and vasoconstrict peripherally to shunt blood centrally. Hypotension is a late finding of shock in previously healthy children, and interventions should ideally occur before the onset of hypotension. 7 The earliest sign of cardiovascular compromise in most patients is tachycardia. Unfortunately, tachycardia is nonspecific and may be due to fever, pain, or anxiety. Repeated assessment of the heart rate can be helpful. In a crying child, a true resting heart rate can be obtained by leaving the pulse oximeter on until the child is calm. Unexplained tachycardia in a calm or sleeping child is concerning. The quality of the pulse is also helpful. A thready peripheral pulse associated with tachycardia should be considered a sign of shock. Bradycardia in ill children is especially ominous and may signal impending cardiac or respiratory arrest.

### Musculoskeletal System

Growing children have musculoskeletal injury patterns different from those of adults. Ligaments are stronger relative to the immature bone, so children are more likely to fracture bones than...
Due to their immature immune system, young infants are at increased risk of serious bacterial infections. Febrile infants younger than 1 month are a particularly high-risk group and have a 10% or higher rate of serious bacterial infection.8-10 For this reason, the evaluation of infants with fever differs from the evaluation of older children and adults; the evaluation varies by age and vaccination status.

**Pharmacologic Considerations**

Medications for children are calculated using weight-based dosing, with attention to the maximum medication dose. Suggested safeguards to prevent calculation-based dosing errors in children include pharmacy review of medication orders, computerized order entry, use of templated order forms, and length-based resuscitation tapes to reduce calculation errors.11,12 One easily remedied potential error is the inadvertent calculation of a drug dose on the basis of weight in pounds, not kilograms, leading to a more than twofold overdose. Therefore, ED scales and electronic charts should be programmed to report weight only in kilograms.

In addition to potential dosing errors, certain frequently used medications in older children and adolescents should not be given to young infants. For example, ceftriaxone is not recommended for infants younger than 28 days because it can displace bilirubin from albumin, leading to kernicterus or bilirubin-induced neurologic dysfunction (BIND). Although not well studied, the use of ibuprofen in infants physical examination younger than 6 months has not been approved by the US Food and Drug Administration because of the theoretical risk of kidney and liver injury.

Modified from The National High Blood Pressure Education Program Working Group on Children and Adolescents: The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. http://r.search.yahoo.com/_ylt=A0LEVjEL_poXnAvA9ecnllIO_ylu=x3oDMTEyMTI4MTejmcmcGlOGvmbGBiYmYxYHtBvcmYMWXH2Os0aWQDQjE4NjFjMQRzZWMc3Ij/RE=1469935735/RU=https%3a%2f%2fwww.nhlbi.nih.gov%2ffile%2fdocs%2fheart%2fhbp_ped.pdf/RK=0/RS=nlJ248BzShav9t19Hzj4KyPU-0/RS=2%

Immunologic System

Due to their immature immune system, young infants are at increased risk of serious bacterial infections. Febrile infants younger than 1 month are a particularly high-risk group and have a 10% or higher rate of serious bacterial infection.8-10 For this reason, the evaluation of infants with fever differs from the evaluation of older children and adults; the evaluation varies by age and vaccination status.

**Pharmacologic Considerations**

Medications for children are calculated using weight-based dosing, with attention to the maximum medication dose. Suggested safeguards to prevent calculation-based dosing errors in children include pharmacy review of medication orders, computerized order entry, use of templated order forms, and length-based resuscitation tapes to reduce calculation errors.11,12 One easily remedied potential error is the inadvertent calculation of a drug dose on the basis of weight in pounds, not kilograms, leading to a more than twofold overdose. Therefore, ED scales and electronic charts should be programmed to report weight only in kilograms.

In addition to potential dosing errors, certain frequently used medications in older children and adolescents should not be given to young infants. For example, ceftriaxone is not recommended for infants younger than 28 days because it can displace bilirubin from albumin, leading to kernicterus or bilirubin-induced neurologic dysfunction (BIND). Although not well studied, the use of ibuprofen in infants physical examination younger than 6 months has not been approved by the US Food and Drug Administration because of the theoretical risk of kidney and liver injury.
Developmental Considerations

Assessment of pediatric patients requires an understanding of normal developmental milestones. Table 160.3 lists basic developmental milestones in the first 2 years of life. Variation in the rate at which children develop can be normal or may signal neurodevelopmental delays. Therefore, the parent’s report of the child’s developmental history and normal behavior is extremely important.

**Young Infants**

Infants younger than 2 months are especially challenging to assess because they have a limited behavioral repertoire. They may not make eye contact or have a social smile. Normal behavior includes sleeping, crying, quiet alert time, feeding, and stooling. A change in any of these activities may indicate serious disease. Increased sleeping or crying or decreased interest in feeding may herald a serious illness, such as sepsis or an underlying cardiac or metabolic disorder.

**Infants (<12 Months)**

Infants typically develop a social smile and track close objects by 2 months of age. After 6 months, infants may develop significant stranger anxiety, making the physical examination challenging. Whenever possible, examining the infant in the parent’s lap, with the infant initially facing away from the examiner, will mitigate anxiety and facilitate physical examination. Bubbles or interactive toys can distract infants and may keep them calm.

**Toddlers (1- to 2-Year-Olds)**

Toddlers have variable reactions to a physical examination. A toddler may provide a limited history due to their narrow expressive language skills (eg, only pointing to the location of pain). Some are fearful and will not cooperate, whereas others are curious and cooperate more easily with the examination. In a stable patient, begin the encounter standing or sitting at a distance from the child while taking the history. Speaking in a soothing voice and distracting the child with toys or other interesting objects can facilitate the examination. Emergency clinicians should interact with the parents, because this will be perceived by the child as a sign of endorsement and indicate that the parents are involved with the emergency care. Conversely, toddlers will often negatively react to parental anxiety.

**Preschoolers (3- to 5-Year-Olds)**

Preschool-age children have increasing language skills. Like toddlers, their receptive language skills exceed their expressive language skills, and they often understand more than is realized. Preschoolers should be included in the conversation when possible. Providers should be cautious about talking to the parents about procedures or diagnoses in front of the preschool child, even if the child seems not to be paying attention or not to understand. Like toddlers, preschool children vary greatly in their cooperation with the physical examination. Providing limited options, such as sitting with the parent or on the gurney, or choosing which ear should be examined first, may give the child a sense of control and improve cooperation. Distraction with stories, videos, or games on a smartphone or other devices can also facilitate the physical examination. The young child will build up anxiety awaiting a procedure. For this reason, providers should provide children with simple concrete explanations of procedures only immediately before and during the procedure. Preschool children may perceive illness or painful procedures as punishment for their actions, making simple explanations of what and why it is occurring even more important.

**School-Age Children**

Some questions during the history should be directed at the school-age child, because many can provide much of the history themselves. At this age, children are often cooperative with the examination, but may regress when they are frightened or in pain. Additionally, children at this age become increasingly modest, and conscious attempts should be made to provide privacy.

School-age children may develop anxiety and attempt to negotiate or stall when a painful or unpleasant examination or procedure is planned, particularly if there is a long delay between the explanation and procedure. Firm but reassuring explanations of what will happen are important. Appropriate concrete explanations include the sequence of events and what physical sensations the patient will experience. It is also crucial to involve parents in the process to provide not only a candid explanation of the procedure itself, but also anticipated reactions from their child. When available, child life specialists are particularly helpful with this age

population, using play and education to prepare children for anxiety-provoking procedures.

Adolescents

Adolescents will be able to provide much, if not all, of the history. However, despite desired independence from their parents, adolescents may regress in times of stress. It is therefore important to elicit the concerns of the adolescent and parent and to ensure that both understand the diagnosis and plan. The adolescent should be given a chance to speak to the provider without the parent in the room. Any sensitive questions, such as those about drug use and sexual activity, should be asked privately.

Adolescents can generally be examined in a manner similar to that for adults. They may or may not prefer to have a parent present during the physical examination, and providers should clarify the patient’s preference. Adolescents are often extremely modest, and attempts should be made to preserve privacy with the examination in a private room, when possible, and exposure of only the body part being examined.

**EVALUATION**

**Triage**

Pediatric-specific triage systems are important to avoid overtriage and undertriage of children. The application of adult-specific vital signs to children will lead to an inappropriate triage level classification. In addition, signs and symptoms of serious illness may be subtle in infants and very young children, requiring those providing the initial triage assessment to be familiar with normal pediatric physiology and development.

Triage systems with pediatric modifications include the Emergency Severity Index, Paediatric Canadian Triage and Acuity Scale, Manchester Triage System, and Australasian Triage Scale.13 No triage system has been clearly demonstrated to be superior, and data on reliability and validity are limited for all triage systems. The Emergency Severity Index, Manchester Triage System, and Paediatric Canadian Triage and Acuity Scale have been demonstrated to be valid for pediatric patients.14–16 Interrater reliability is good for the Manchester Triage System and moderate for the Emergency Severity Index and Paediatric Canadian Triage and Acuity Scale.13,14 The Australasian Triage Scale appears to have lower reliability than the other triage systems.13

**History**

In critically ill or injured patients, the SAMPLE history can be used to obtain a focused history quickly (Box 160.2). The SAMPLE history reminds providers to ask for Signs and symptoms, Allergies, Medications, Past medical history, Last meal, and Events surrounding the illness or injury.

**BOX 160.2**

**Focused SAMPLE History**

- Signs and symptoms
- Allergies
- Medications
- Past medical problems
- Last food or liquid
- Events leading to injury or illness

A more detailed history will be guided by the patient’s presenting complaint. In preverbal children, symptoms will often be inferred by the caregiver based on the child’s behavior. Parents are often very perceptive and may notice subtle changes in behavior that are not immediately evident to a healthcare provider.

Additional age-specific questions may be indicated. In neonates, pregnancy and birth history will help identify risk factors for conditions such as hyperbilirubinemia (eg, prematurity, ABO incompatibility), infection (eg, maternal fever during labor, early rupture of membranes, maternal group B streptococcus status), and respiratory illnesses (eg, prematurity, meconium aspiration, need for supplemental oxygen or mechanical ventilation). In infants and toddlers, urine output, quantified by the number of wet diapers, helps determine hydration status. This can be especially helpful in breast-feeding newborns, whose intake is difficult to quantify. Vaccination status is important in infants and children presenting with symptoms such as fever (eg, risk of bacteremia) and rash (eg, risk of varicella, measles). Drug and alcohol use, as well as the sexual history, become important in adolescents who have increased risk-taking behaviors and should be questioned in a private setting, not in front of the caregiver.

**Pediatric Assessment Triangle**

Rapid recognition of the critically ill child is a crucial skill. The pediatric assessment triangle (PAT) assists providers in assessing children quickly and is an orderly approach for formulating an initial impression of the child’s overall status from the door of the examination room13–16 (Fig. 160.2). The three components of the PAT are (1) appearance, (2) work of breathing, and (3) circulation. On the basis of the initial PAT, the emergency clinician can distinguish the “sick” from the “well” child rapidly. Table 160.4

**Table 160.4**

Normal pediatric respiratory rates are inversely related to age due to younger children's increased metabolic rates and lower tidal volume reserves. Because children normally function near their maximum tidal volume capacity, relatively small increases in metabolic demands (e.g., fever) can result in an elevated respiratory rate.

summarizes the findings that may be noted on each of the three sides of the triangle, and Table 160.5 summarizes interpretation of the PAT.

**Appearance**

Observation of the child from a distance allows the provider to assess the patient's overall status without upsetting the child. The mnemonic TICLS (tone, interactiveness, consolability, look and gaze, speech and cry) summarizes the components of the assessment of overall appearance. Observation of the infant or child interacting with his or her parents provides many clues about the child's overall status. An ill infant with a vacant or glazed look can be distinguished from an alert infant who responds to environmental stimuli. An infant who is awake but lying motionless on a gurney is much more concerning than an active infant who moves all the extremities. Irritability is an early sign of inadequate brain perfusion. This may be followed by lethargy and then coma as perfusion is further compromised.

The quality of the cry is another helpful clue. A persistently high-pitched or irritable cry is concerning for central nervous system disease, such as meningitis. A normal overall appearance suggests that oxygenation, ventilation, and perfusion are adequate.

**Work of Breathing**

The work of breathing should initially be observed from a distance because it is difficult to accurately assess work of breathing in a crying child. Infants and children with respiratory distress may assume the sniffing position in an attempt to decrease their work of breathing. The tripod position is an ominous sign of severe respiratory distress.

The quality of the voice or cry may be a clue to airway and respiratory disease or compromise. For example, children with croup have a hoarse voice, and children with peritonsillar abscesses may have a muffled or so-called hot potato voice. Abnormal breath sounds may be audible without a stethoscope.

Signs of respiratory compromise include stridor, audible wheezing, retractions, grunting, and snoring respirations. To assess the presence of retractions and abdominal breathing, the infant or young child should be observed with the chest unclothed. Retractions may be seen in the suprasternal, supraclavicular, intercostal, and subcostal areas (Fig. 160.3). Nasal flaring is an attempt to decrease airway resistance (Fig. 160.4). Head bobbing (the use of neck muscles to assist respiration) and seesaw breathing (ineffective breathing pattern, in which the abdomen moves outward while the chest moves inward during inspiration) are signs of impending respiratory failure. As the child tires and nears complete respiratory failure, the respiratory rate falls and the work of breathing may diminish.

As a result, abnormal respiratory patterns may provide clues about a nonrespiratory illness. Effortless tachypnea may be a sign of shock from any cause, whereas deep rapid breathing without other auscultative findings may be compensation for a metabolic acidosis. Children who are tachypneic despite normothermia must be evaluated for respiratory and nonrespiratory causes. Neurologic disorders may also lead to abnormal respiratory patterns (eg, bradypnea and respiratory irregularity in the setting of increased intracranial pressure).

Circulation

Visual inspection of the skin can provide clues to overall cardiovascular status. Early compensated shock is characterized by peripheral vasoconstriction and shunting of blood to the brain and other vital organs. At this stage, skin appears pale but remains warm to the touch with delayed capillary refill time (>2 seconds). If the shock state is not corrected, the patient may become mottled, with cold extremities (Fig. 160.5A). Mottling is a random pattern of vasoconstriction in adjacent capillary beds in the skin. This is not to be confused with cutis marmorata, a lacy pattern on the skin caused by vascular instability (see Fig. 160.5B). Cutis marmorata is a normal finding in young infants in a cool environment. In contrast to infants with mottling, infants with cutis marmorata will be otherwise well-appearing, and the skin findings will diminish or disappear if the infant is placed in a warm environment. Cyanosis may be present normally in children with congenital heart disease but, if cyanosis is a new finding for the patient, it is almost always indicative of respiratory failure or decompensated shock.

Length-Based Resuscitation Tape

An accurate weight is often not available for critically ill children. Use of a color-coded, length-based resuscitation tape gives an estimate of the child’s weight. Each color on the tape corresponds to a weight range that corresponds to an ideal body weight for length. Medication doses and appropriate equipment are listed on the tape for each weight range. Use of the length-based resuscitation tape avoids error-prone calculations of medication dosages and equipment sizes in the high-stress setting of a pediatric resuscitation. In addition, pediatric resuscitation equipment organized by weight ranges minimizes the need to search for appropriately sized equipment.

Physical Examination

As in adults, the physical examination in critically ill or injured children will focus initially on airway, breathing, and circulation, with abnormalities in these systems corrected before a complete physical examination is performed. In any infant or toddler with respiratory complaints, observing the child breathing with the shirt removed will allow the most reliable assessment of the work of breathing. The respiratory rate should be manually counted for a minimum of 30 seconds, due to periodic breathing, and also because the rate on the monitor can be unreliable. In infants and young children with some degree of respiratory distress, observation of respiratory status and pulse oximetry during feeding or sleeping can be helpful when deciding on further observation and admission.

In infants and young children, the physical examination should not be performed in a head to toe fashion. Auscultation of the heart and lungs and palpation of the abdomen should be performed before other more frightening or uncomfortable parts of the examination. Although, ideally, the physician should palpate the child’s abdomen, occasionally a fearful child will cry so much it is impossible to determine if the child has abdominal tenderness or guarding. In these cases, observing the parent palpate the abdomen can be helpful. Although parents cannot be relied on to examine for masses or organomegaly, they can elicit pain with palpation and feel for guarding.

Examination of the ears, oropharynx, or area of injury should occur toward the end of the physical examination. Providers can try to ease a child’s fear by first demonstrating the examination on a parent, older sibling, or stuffed animal. For the ear examination, the parent can hold the young child in his or her lap, with one arm around the head and one arm around the child’s body and arms (Fig. 160.6). Young children can often be coaxed into opening the mouth wide enough for examination of the oropharynx without use of a tongue depressor. The examination can be turned into a game by asking the child to open his mouth and pant “like a puppy” or see if she or he can touch the tongue to the chin. When necessary, external examination of the vagina in young girls can be facilitated by having them sit in a frog leg position in the parent’s lap. Children should be reassured of the safe environment with the provider and caregiver but also should be counseled to understand the difference between the examination and inappropriate touching by others.

**SPECIFIC DISORDERS**

The most common reasons for infants and children to present to EDs are respiratory illness, fever, and injury. Causes of serious illness and injury vary by age. Respiratory illnesses are the most common reason for infant hospitalization after the
immediate neonatal period. Asthma and appendicitis are the most common reasons for hospitalization of school-age children, and affective disorders are the most common cause of adolescent hospitalizations.

This section focuses on complaints specific to the pediatric population and complaints in which the differential and approach vary significantly from those in adult populations.

**Common Neonatal Complaints**

Neonates may present with a variety of previously undiagnosed genetic, anatomic, and metabolic conditions. In addition to the limited behavioral cues displayed by newborns, parents of newborns are frequently anxious and may not know what behaviors or patterns are normal.

Concerns about feeding are common. Neonates typically feed every 2 to 3 hours. Bottle-fed neonates take about 2 to 3 ounces per feed, whereas breast-feeding neonates typically spend 10 to 15 minutes on each breast each feed. Newborns, especially those who are exclusively breast-fed, can lose up to 10% of their birth weight during the first 7 days of life. Birth weight should be regained by day 10, with a subsequent weight gain of 20 to 30 g/day for the first 3 months of life. Providers should clarify feeding routines with caregivers. Infants with excessive weight loss or failure to gain weight may have underlying metabolic, cardiac, or infectious causes or be victims of abuse or neglect.

Small amounts of regurgitation of breast milk or formula are normal in infants and generally are not concerning if the amount is stable, the infant is gaining weight, and emesis is not bilious. Larger volume emesis must be evaluated. Common benign causes include overfeeding and inadequate burping, but providers should consider other serious causes, such as pyloric stenosis, volvulus, intussusception, and nonaccidental trauma (head or abdominal). Another common concern is the frequency and consistency of bowel movements. Although infants typically have soft stools multiple times a day, it can be normal for exclusively breast-fed infants to stool as infrequently as once every 5 to 7 days. Straining during a bowel movement is also commonly seen and may occur after transition from breast milk to formula. In infants presenting with constipation, a history of failure to stool in the first 24 hours of life is concerning for Hirschsprung’s disease—aganglionic segments of the colon that fail to relax.

**Neonatal Intensive Care Unit Graduate**

Gestational rather than chronologic age is typically used for premature infants in whom development is often delayed. Due to their immature immune function relative to infants of the same chronologic age, premature infants are at increased risk for recurrent respiratory infections. Chronic lung disease is a common complication in extremely premature infants (gestational age < 28 weeks). Such infants frequently have a baseline tachypnea and increased work of breathing and may require supplemental home oxygen. Parental report of changes in work of breathing, activity, feeding pattern, and level of alertness can be clues to serious illness, such as sepsis or underlying metabolic abnormalities.

Respiratory syncytial virus (RSV) immunoglobulin (palivizumab) prophylaxis is recommended for certain high-risk infants during peak season. During RSV season, the timing of the last RSV immunoglobulin injection given should be ascertained when a premature infant presents with fever, cough, or rhinorrhea. Palivizumab is administered monthly and, if a dose has been missed, the physician should have a higher level of suspicion for RSV infection.

**Children With Special Health Care Needs**

The assessment of children with chronic illnesses and other special health care needs is especially challenging. Parents or other daily caregivers can provide helpful information on baseline behavior and mental status, and the caregiver’s input should be sought.

However, a parent’s knowledge and recollection of detailed medical information may be limited, especially during times of high stress. Parents may forget medication names or concentrations, details of previous hospital admissions, and current treatment plans. An Emergency Information Form (EIF) that summarizes chronic medical conditions, medications, medical devices, and other critical information can be used for children with special health care needs (available at www.acep.org/clinical-practice-management/emergency-information-form-for-children-with-special-health-care-needs). These forms can quickly provide critical information to the ED provider, assisting in the early management and stabilization of the child until more detailed records are obtained. ED staff can request that specialists affiliated with their hospitals provide EIFs for complex patients to facilitate rapid and appropriate emergency treatment.

**Child Abuse**

Nonaccidental trauma should be a consideration for all patients presenting with injuries and complaints, such as altered mental status and apparent life-threatening events. Unfortunately, abusive injuries are frequently not recognized at the initial health care encounter, leaving children at high risk for future and more serious injuries and death. Historical clues to nonaccidental trauma include mechanisms inconsistent with the injury pattern or a history inconsistent with the developmental level of the child (Box 160.3). Physical examination clues for abuse include presence of bruises in young prewalking infants and unusual locations of bruises, such as the ear and trunk (Box 160.4). Fractures in children younger than 12 months without a significant witnessed trauma mechanism are especially concerning. For a more detailed description of the evaluation of suspected child abuse.
for the premature neonate to the adult-sized adolescent. The American College of Emergency Physicians, American Academy of Pediatrics, and Emergency Nurses Association have developed joint guidelines for the care of children in the ED.\(^{30,31}\) The guidelines include recommendations for necessary personnel, protocols, medications, equipment, and supplies. Surveys have found that EDs frequently lack the items recommended in the guidelines.\(^{32}\) One strong recommendation in the guidelines is the appointment of physician and nurse coordinators for pediatric emergency care.\(^{32,33}\)

Pediatric emergency readiness also requires a plan for continuing care of critically ill and injured children. Small community hospitals often do not have pediatric intensive care units or access to pediatric subspecialists. Therefore, a plan for transfer of patients whose needs exceed available resources is necessary. Receiving hospitals and a mechanism for transporting critically ill pediatric patients should be identified in advance.

### Pediatric-Friendly Emergency Department

One topic that has received increasing attention is pain and anxiety management in pediatric patients. Procedural pain is frequently undertreated in infants.\(^{33,34}\) Appropriate use of sedation, anesthesia, analgesia, and nonpharmacologic methods of pain management can increase the patient’s cooperation and increase visit satisfaction for the child and parent. Children have significant anxiety and fear surrounding medical procedures, leading to additional challenges in performing procedures successfully. In addition to reducing pain and anxiety during the acute visit, adequate pain control is likely to have long-term benefits. Multiple studies have demonstrated that inadequate procedural pain control can lead to increased pain perception with future painful procedures.\(^{35}\)

A variety of options are available to minimize pain associated with blood draws and intravenous line starts, including vapocoolants, topical anesthetics, and needle-free jet injection of anesthetics.\(^{36}\) Topical anesthetics can also decrease the pain of an anesthetic injection before a lumbar puncture and other procedures. Topical application of a lidocaine, epinephrine, and tetracaine mixture has been shown to have comparable efficacy to injected anesthesia for facial and scalp lacerations.\(^{37}\) The combination of sucrose and radiant warmth can provide effective analgesia to newborns.\(^{38,39}\) Child life specialists are particularly helpful and, when available, should be used to provide play therapy and education to frightened children, allowing the provider to focus on the procedure singularly. Child life providers use nonpharmacologic distraction techniques such as bubbles, songs, books, videos, and video games to decrease anxiety, tools that can also be adopted by department staff.\(^{36}\) In young children, the use of anxiolytic medications or procedural sedation may be appropriate for procedures that could be accomplished with local anesthesia in older patients.

Another shift in has been in regard to increased support for the family’s presence during invasive procedures and resuscitations.\(^{40}\) Children are stressed when separated from their parents, and one benefit of a family’s presence is to reassure and calm the child. Studies have shown that a family’s presence also decreases anxiety levels in family members.\(^{41}\) Their presence during unsuccessful cardiopulmonary resuscitation is perceived by families as beneficial in the grieving process. Studies have shown that with well-implemented policies, a family’s presence does not interfere with resuscitation.\(^{42}\)

Families present during resuscitations should have a family support person assigned who can explain procedures and answer questions. Ideally, families are briefed on what to expect before entering the resuscitation room. Guidelines have been developed to assist emergency clinicians in implementing family presence protocols at their institutions.\(^{42}\)

---

**BOX 160.4**

**Physical Examination and Radiologic Findings Concerning for Abuse**

- Any bruises in young precruising infants
- Patterned ecchymosis, burns, or skin marks (abrasions, lacerations)
- Bruises on the ears, trunk, inner thighs, neck, or groin
- Posterior oropharynx bruising or lacerations
- Posterior rib fractures
- Classic metaphyseal fractures
- Any fracture in a nonambulatory child
- Fractures in different stages of healing

---

**OTHER CONSIDERATIONS**

**Consent for Emergency Care**

In general, parent or guardian consent is required for the evaluation and treatment of minors and emergency clinicians should attempt to notify parents or guardians and obtain consent. However, in emergent situations, evaluation and stabilization cannot be delayed while awaiting consent. The Emergency Medical Treatment and Active Labor Act has mandated that patients presenting for emergency care receive a medical screening examination and, if an emergency medical condition is identified, patients should receive the care required to stabilize the condition.\(^{29}\) Thus, all minors presenting to the ED require an examination to determine if an emergency medical condition exists. If a condition that is threatening to life or health exists, treatment should be provided under the doctrine of implied consent. If an emergency medical condition is not suspected after a screening examination, nonemergent care should be delayed until guardian consent is obtained, unless the minor is legally able to consent for care.

The circumstances under which minors can consent for their own care vary from state to state, but minors can generally consent if they are emancipated or if they are seeking treatment for mental health issues, drug or alcohol abuse, contraception, pregnancy, or testing for or treatment of sexually transmitted infections.\(^{29}\)

Minors are generally considered emancipated if married, on active duty in the military, or living independently and economically independent from their parents. Some states recognize minors as emancipated if they are pregnant or a parent. Many states recognize that a mature minor, generally 14 years or older, can consent for care if sufficient intelligence and maturity is displayed to make a reasonable and voluntary choice. The process for determining mature minor status varies from state to state.

**Pediatric-Ready Emergency Department**

Preparation to care for infants and children of all ages involves not only ED staff training but also stocking pediatric medication formulations, equipment, and supplies in appropriate sizes.
Chapter 160: General Approach to the Pediatric Patient

Patterns of illness and injury vary by age, and a number of anatomic and physiologic characteristics affect the presentation and management of pediatric emergencies.

A basic understanding of normal development will aid the emergency clinician in assessment of the pediatric patient.

The pediatric assessment triangle (PAT) can be used as a tool for rapid evaluation of the patient’s overall status.

Tachypnea in children must be evaluated relative to age norms and is often a sign of increased metabolic demands. A child with tachypnea despite normothermia should be evaluated for respiratory and nonrespiratory causes (e.g., hypoperfusion, acidemia).

Maintenance of a neutral thermal environment is necessary for critically ill infants.

Child abuse should be considered when injuries are inconsistent with history, when details of the history change, or with certain injury patterns.

A joint guideline of the American College of Emergency Physicians, American Academy of Pediatrics, and Emergency Nurses Association summarizes the role of pediatric emergency care coordinators, development of pediatric policies, and recommended equipment, supplies, and medications for EDs.

The family’s presence should be encouraged for pediatric procedures and resuscitations.

A variety of pharmacologic and nonpharmacologic techniques are available to decrease procedural pain and anxiety.

REFERENCES

39. American Academy of Pediatrics Committee on Infections Diseases, American Academy of Pediatrics Bronchiolitis Guidelines Committee: Updated guidance for the following respiratory signs is characteristic of a child in compensated or decompensated shock?

A. Grunting with abnormal breath sounds

B. Tachypnea with nasal flaring

C. Tachypnea without aberrant breath sounds on auscultation

D. Tripoding with stridor

E. Wheezing with retractions

Answer: B. Effortless tachypnea, or rapid respirations with clear breath sounds, is characteristic of a child in compensated or decompensated shock. Grunting, nasal flaring, tripoding, stridor, wheezing, and retractions are all signs of increased work of breathing and would be more indicative of pulmonary or airway disease.

160.2. As the pediatric physician coordinator for your emergency department, you decide to institute new policies to prevent pediatric medication errors. Which of the following strategies will be most effective in decreasing risk of dosing errors?

A. Pharmacy review of medication orders

B. Use of length-based resuscitation tapes

C. Use of resuscitation calculators

D. Weighing and recording the weight in kilograms

Answer: D. Weights should be measured and recorded in kilograms, not pounds, to avoid inadvertent dosing calculations using pounds instead of kilograms. The use of length-based resuscitation tapes and resuscitation calculators and pharmacy review of medication orders have also been suggested to reduce medication errors.
dosing errors, but the most effective measure is to weigh and record the weight in kilograms.

160.3. You have written an order for a blood draw and placement of an intravenous line in a nervous 3-year-old boy. Which of the following is least likely to be helpful in decreasing the patient’s procedure-related distress?
A. Application of a lidocaine-epinephrine-tetracaine mixture
B. Having the patient blow bubbles prior to the needle stick
C. Needle-free jet injection of local anesthetic
D. Use of a vapocoolant

Answer: A. The formulation of lidocaine-epinephrine-tetracaine only works on broken skin (ie, lacerations). Unlike eutectic mixture of local anesthetic (EMLA) and 4% liposomal lidocaine preparations which are effective on intact skin, it will not work on intact skin. The use of vapocoolants and a needle-free jet injection of local anesthetic may decrease the patient’s pain. Distraction techniques such as blowing bubbles, singing a song, or watching a video may relieve procedure-related anxiety.
CHAPTER 161

Airway Management for the Pediatric Patient

Joshua Nagler | Nathan W. Mick

PRINCIPLES

Although there are similarities in the skills required to perform endotracheal intubation in adults and children, anatomic and physiologic differences in children should be understood and mastered. These differences are most prevalent in the first 2 years of life and necessitate modifications to the intubation approach in older adolescents and adults. Additionally, because of the size and weight spectrum inherent in the pediatric patient population, there is a spectrum of equipment selection and medication dosages.

Management of the pediatric airway is a critical intervention, although infrequently required, making skill acquisition and retention difficult for emergency clinicians. Even in large children’s hospitals, there are few opportunities to perform endotracheal intubation as part of clinical practice. Of 1000 pediatric emergency department (ED) patients, 1 to 3 will require intubation, compared to 1 out of 100 adults. Many providers will leave residency training with fewer than 10 pediatric intubations and will not routinely intubate children as part of their clinical practice after training. At the same time, pediatric intubation success and skill mastery improves with increasing experience. Operating room studies demonstrate first-pass intubation success rates are less than 50% after 10 airways but rise to more than 90% after 50 intubation attempts. Fortunately, through experience with older patients, most emergency providers can recognize critical illness and have the skills necessary to manage the pediatric airway. These translational skills can be augmented using a simulated environment or with dedicated training in the operating room. Developing a systematic approach to pediatric airway management while recognizing the anatomic and physiologic differences in the young child will be critical to success and eliminate many of the anxieties associated with performing a time-dependent, infrequent critical action.

ANATOMY

There are several anatomic differences in pediatric patients which directly impact airway management (Table 161.1). These differences are most notable in the first 2 years of life; children 2 to 8 years old represent a transitional stage where the anatomy becomes more adult-like, yet variability with medication dosing and equipment size selection remain. Although infants and children are predictably different than the adult population, they are not inherently difficult with regards to airway management.

Aligning the oral, pharyngeal, and laryngeal axes is critical to visualization of the glottis during direct laryngoscopy, and correct positioning of the patient can facilitate alignment. The small infant has a relatively large head and occupent in relation to their body size. This can cause slight flexion at the neck when the patient is lying supine, impeding the ability to visualize the glottis. The patient should be positioned so that a line drawn through the external auditory canal and the anterior shoulder is horizontal and parallel to the bed (Fig. 161.1). In the infant (younger than 6 months old), this is accomplished by placing a towel roll under the patient’s shoulders, elevating the body, and overcoming the flexion associated with their large occiput. In the small child (6 months to 3 years old), correct positioning can likely be achieved without the need for support. In the older child/adolescent, the head is smaller in relation to the size of the body and the head may need to be elevated. As long as cervical spine injury is not suspected, correct positioning combined with slight extension at the neck will optimize the conditions for direct laryngoscopy.

Infants and children have large tongues relative to the size of their mouths and tend to have a large, floppy epiglottis. Because of these differences in anatomy, they are prone to obstruction when sedated or obtunded and manipulation of the epiglottis during direct laryngoscopy is frequently required to achieve intubation. Practically, these differences may necessitate the use of an oral or nasopharyngeal airway during bag-mask ventilator (BMV) ventilation to bypass the large tongue. Furthermore, a straight (Miller) laryngoscope blade may better manipulate the floppy epiglottis.

The vocal cords and glottic opening are situated at the level of the first cervical vertebrae in infants, gradually drop to the C3 to C4 level by age 7 and further descend to the C6 level by late adolescence. Therefore, the airway is higher and more anterior in small infants than what is encountered in adults, making correct positioning prior to direct laryngoscopy critical to ensure success of intubation (Fig. 161.2).

Historically the narrowest portion of the pediatric trachea was felt to be subglottic at the cricoid ring. Recent studies in anesthetized pediatric patients demonstrate anatomic narrowing at the level of the vocal cords and an elliptical-shaped subglottic region. Because of the non-distensible nature of the cricoid cartilage, the subglottic region functionally remains the narrowest in the spontaneously breathing child.

The unique anatomy of the pediatric upper airway has led to the use of uncuffed endotracheal tubes (ETTs) in the small child. Support for uncuffed tubes came at a time when the cuffs were relatively stiff and there was not a reliable, easy way to identify high cuff pressures that can lead to subglottic tracheal injury. Current cuff technology can accurately measure cuff inflation pressures, and cuffed tubes may be preferred, particularly in instances of high airway pressures or poor compliance (eg, asthma, pneumonia, and acute respiratory distress syndrome [ARDS]). Utilizing a cuffed ETT may obviate the need to replace and upsize a tube when there is significant air leak that impacts ventilation.

The pediatric trachea is more flexible and prone to dynamic collapse. In addition to implications with positioning during assisted BMV and intubation, the trachea can collapse without complete obstruction with upper airway pathology (eg, croup, bacterial tracheitis). In cases of upper airway pathology, keeping

**Fig. 161.1.** Correct positioning of a pediatric patient to ensure optimal airway alignment utilizing a line passing through the external auditory canal and the anterior shoulder. A, The small infant requires a shoulder roll to achieve optimal positioning, the small child typically requires neither a shoulder roll nor head support, and the older child/adolescent may require head support. B, In this small child, a line drawn through the external auditory canal and the anterior shoulder reveals the child to be in good position without support. Slight extension of the head results in the achievement of the sniffing position. (Used with permission: Walls R, Murphy M: Manual of emergency airway management, ed 4, Philadelphia, 2012, Lippincott Williams & Wilkins.)
the patient in a calm and quiet environment is important. Cases of “complete” upper airway obstruction in pediatrics often respond well to the addition of positive pressure via BMV, which can act to stent open the upper airway. Heliox, typically a 70% to 30% mixture of helium to oxygen, increases laminar flow in obstructed airways. A trial of heliox may be considered in cases of partial upper airway obstruction (eg, croup), although it has been found no more effective than racemic epinephrine or humidified oxygen in reducing the level of distress in these patients.3

The anatomic variations in children impact recommendations in pediatric airway management. Children have relatively prominent tonsillar and adenoidal tissue that is prone to bleeding with even minor trauma. Thus, blind nasotracheal intubation is relatively contraindicated and not routinely recommended in pediatric patients younger than 10 years old. Anatomical landmarks may be difficult in young infants and children with short necks with prominent soft tissue and with a small cricothyroid membrane, resulting in needle cricothyrotomy as the recommended invasive airway of choice rather than surgical cricothyrotomy.

Finally, small children are dependent on diaphragmatic excursion for ventilation and have relatively large stomachs and low gastroesophageal sphincter tone. They are predisposed to gastric insufflation during BMV attempts, which can impede diaphragmatic motion and compromise ventilation. Use of cricoid pressure in infants and young children is controversial and not well supported in the literature. If gentle cricoid pressure is used during BMV and chest rise is poor, we recommend release of cricoid pressure to see if effective ventilation can then be maintained. We recommend placement of a nasogastric or orogastric tube and aspiration of air immediately following endotracheal intubation or before intubation if the abdomen is becoming distended and impeding ventilation during BMV.

**PHYSIOLOGY**

Owing to a high metabolic rate and low functional residual lung capacity, young children are prone to quick desaturation once apneic, even with preoxygenation. Whereas a fully preoxygenated adult with healthy lungs may not desaturate below 90% for a full 6 minutes, a normal healthy 10-kg child may fall below 90% in half that time and a sick infant may desaturate in less than 1 minute. Thus, careful attention to preoxygenation is crucial. Additionally, use of high-flow nasal cannula (15 L/min for children and 5 L/min for infants) during the apneic period may help support oxygenation until intubation can be achieved. BMV should be provided between intubation attempts when oxygen saturation levels start to decline below 95%.

Children have a large extracellular fluid volume when compared with adults. Many of the drugs used to facilitate endotracheal intubation (sedatives and paralytics) need higher per kilogram doses; their duration of action may also be shorter when compared with adults.

**EQUIPMENT**

The cognitive burden that occurs when caring for a critically ill child is significant. Equipment selection and medication dosing must be calculated based on weight and size, which can vary tremendously across the spectrum of pediatric patients, from the 3 kg newborn to the 100 kg adolescent. Every ED that cares for pediatric patients should have airway equipment stocked, accessible, and organized by age and size to facilitate easy use. There are many systems, such as the Broselow-Luten system, to facilitate this organization (Fig. 161.3). Regardless of the system, elimination of the reliance on rote memorization lessens the cognitive burden of caring for pediatric patients across the age/size spectrum.

There are several “formulas” that are useful in selecting the appropriate equipment for pediatric patients. To determine ETT size, a number of methods are used. Measure the length of the child with a length-based resuscitation tape that has tube sizes based on length and weight recorded on the tape, or use of age-based formulas for a child older than 1 year old:
**The Broselow-Luten Zones for Pediatric Drugs and Equipment**

The Broselow-Luten zones for pediatric drugs and equipment are color-coded to help with quick identification and dosing. The zones are based on weight and length, with each zone representing a specific range of weight and length.

### Zone 3 kg - 4 kg
- LMG (cm): 46-52
- Weight (kg): 3
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 0.9 mg
- Paralysis: Succinylcholine 6 mg
- Maintenance: Lorazepam 0.15 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 50 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 20-30
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 4 kg - 5 kg
- LMG (cm): 52-57
- Weight (kg): 4
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 1.2 mg
- Paralysis: Succinylcholine 8 mg
- Maintenance: Lorazepam 0.4 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 50 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 24-40
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 5 kg - 6 kg
- LMG (cm): 57-61
- Weight (kg): 5
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 1.5 mg
- Paralysis: Succinylcholine 10 mg
- Maintenance: Lorazepam 0.9 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 50 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 30-50
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 6 kg - 7 kg
- LMG (cm): 61-67
- Weight (kg): 6
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 2 mg
- Paralysis: Succinylcholine 13 mg
- Maintenance: Lorazepam 1 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 50 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 40-65
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 7 kg - 8 kg
- LMG (cm): 67-75
- Weight (kg): 7
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 2.5 mg
- Paralysis: Succinylcholine 17 mg
- Maintenance: Lorazepam 1.3 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 60-80
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 8 kg - 9 kg
- LMG (cm): 75-85
- Weight (kg): 8
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 3.2 mg
- Paralysis: Succinylcholine 20 mg
- Maintenance: Lorazepam 1.7 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 80-105
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 9 kg - 10 kg
- LMG (cm): 85-97
- Weight (kg): 9
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 4 mg
- Paralysis: Succinylcholine 26 mg
- Maintenance: Lorazepam 2 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 105-130
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 10 kg - 11 kg
- LMG (cm): 97-109
- Weight (kg): 10
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 5 mg
- Paralysis: Succinylcholine 33 mg
- Maintenance: Lorazepam 2.1 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 130-165
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 11 kg - 12 kg
- LMG (cm): 109-121
- Weight (kg): 11
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 5.5 mg
- Paralysis: Succinylcholine 40 mg
- Maintenance: Lorazepam 3.3 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 165-210
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 12 kg - 13 kg
- LMG (cm): 121-133
- Weight (kg): 12
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 6 mg
- Paralysis: Succinylcholine 53 mg
- Maintenance: Lorazepam 3.3 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 210-265
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

### Zone 13 kg - 14 kg
- LMG (cm): 133-146
- Weight (kg): 13
- Pretreatment: Atropine 0.1 mg
- Induction: Etomidate 6.3 mg
- Paralysis: Succinylcholine 66 mg
- Maintenance: Lorazepam 3.3 mg
- Equipment: ETT (mm) 3.5 unc/3.0 cuff
- Suction: 8 F
- L-scope blade: 1 St.
- Oral airway: 60 mm
- NP airway: 14 F
- ETCO2 detector: PED
- BMV (min vol mLs): 450
- LMA: 1
- Ventilation: Tidal volume mL 265-330
- Frequency (bpm): 20-25
- Insp time (sec): 0.6

*Midazolam is the same dose as etomidate.

**Fig. 161.3.** The Broselow-Luten zones for pediatric drugs and equipment. BMV, bag-mask ventilator; ETCO2, end-tidal carbon dioxide; ET, endotracheal tube; FiO2, fraction of inspired oxygen; LMA, laryngeal mask airway; NP, nasopharyngeal; PED, pediatric; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure; RR, respiratory rate; RSI, rapid sequence intubation; SO2, succinylcholine.
Example: 4-year-old patient
\[ 4 + (4 \text{ years} / 4) = 5.0 \text{ uncuffed ETT} \]

or

\[ 4.5 \text{ cuffed ETT} \text{ (subtract 0.5 from above formula for cuffed tube sizing)} \]

ETT depth of insertion (lip to tip distance) can be estimated by use of the Broselow-Luten tape or by the following formula:

\[ 3 \times \text{ uncuffed tube size} = \text{lip to tip distance (mid-trachea)} \]

Example: 5.0 ETT

\[ 3 \times 5.0 = 15 \text{ cm depth of insertion} \]

For a child who is effectively stabilized using noninvasive means (such as, BMV), the additional benefit of a secure airway needs to be weighed against the risk of potential difficulty or complications. The rapidity with which this decision needs to be made varies depending on circumstances. Failure to successfully oxygenate or ventilate a child by other means forces immediate action, whereas other conditions allow medical interventions and recurrent assessments over time to determine if advanced airway management is required.

Overall an equal number of pediatric intubations in the ED are performed on trauma and nontrauma patients. Indications for pediatric intubation can be placed into four categories: (1) inability to oxygenate and ventilate a child by other means forces immediate action, whereas other conditions allow medical interventions and recurrent assessments over time to determine if advanced airway management is required.

Respiratory compromise is a leading contributor to morbidity and mortality in the pediatric population and more likely than a primary cardiac disease to be the cause of arrest. Respiratory failure can result from intrinsic pulmonary disease or from conditions with infectious, neuromuscular, traumatic, toxicologic, or environmental etiologies. Respiratory failure is a clinical diagnosis, identified by characteristic examination findings and supported by noninvasive measurement of oxygenation (pulse oximetry) and ventilation (capnography). Blood gas analysis can also be informative but should not be relied upon to determine need to perform necessary advanced airway management.

Signs of partial obstruction (sonorous or stridulous airway noises) or complete obstruction (inability to phonate or produce audible breath sounds in a patient with an adequate respiratory effort) suggest an inability to maintain the airway and should prompt immediate basic airway maneuvers, including airway repositioning or oral and nasal airways used to help stent open the upper airways. Suctioning and removal of any foreign material might also be required. When these efforts are ineffective, patients may require an advanced airway. For patients with severely depressed mental status, the loss of protective airway reflexes necessitates airway control, regardless of the ability to maintain the airway. In fact, the use of a Glasgow Coma Score (GCS) of 8 or less is often cited as an indication for intubation in head-injured patients. Systemic illness, toxicologic exposure, and other etiologies of central nervous system (CNS) depression may also increase risk of aspiration, and the presence of a gag reflex correlates poorly with GCS and the risk of aspiration; thus testing for it is not recommended, because it may increase the risk of vomiting and subsequent aspiration.

When airway compromise is progressive (eg, from thermal injury or anaphylaxis), airway management should be initiated early to avoid respiratory embarrassment and increased difficulty later in securing the airway. Similarly, patients with systemic illnesses (such as, sepsis) may be intubated based on their anticipated course, as well as to maximize oxygen delivery and offload metabolic demands related to increased work of breathing.

Children often require sedation to perform diagnostic testing, such as computed tomography (CT), magnetic resonance imaging (MRI), or invasive procedures. The risk of airway compromise during procedural sedation is greater in patients with significant illness or medical instability. Therefore, securing the child’s airway may be necessary to ensure safety during the procedure, particularly in circumstances where accessibility for assessment and intervention may be compromised, such as if a patient will be under surgical drapes or tunneled into a CT or MRI scanner. Because many acutely ill and injured children will require transfer to a pediatric tertiary care center, the stability of the patient’s overall condition and risk of airway compromise should be carefully considered. Securing the airway prior to transfer can obviate the need for emergent advanced airway management in a less controlled setting.

**MANAGEMENT**

**Rapid-Sequence Intubation**

Rapid sequence intubation (RSI) is the preferred method to perform endotracheal intubation in children, provided no contraindications exist. There may be a temptation to attempt emergency pediatric endotracheal intubation with sedation only, but studies have demonstrated higher success and lower complications rates with RSI. A small number of medications are used for pretreatment, sedation/induction, and neuromuscular blockade during ED pediatric RSI (Table 161.2).

**Pretreatment**

The goal of pretreatment medications is to attenuate the physiologic responses to laryngoscopy and intubation, or to mitigate the adverse effect of pharmacologic agents used for sedation or neuromuscular blockade. It is important to note that data are limited with regard to the benefit of pretreatment medications in children. In addition, use of these agents needs to be weighed against the potential for procedural delays and drug errors that can occur with the administration of weight-based medications. This is particularly relevant during high stress situations, such as the management of critically ill children. Two drugs have been used for pretreatment in pediatrics: (1) atropine to prevent bradycardia related to vagal tone, and (2) lidocaine to attenuate the reflex sympathetic response in patients with concern for increased intracranial pressure (ICP); however, their use today is not routinely recommended.

Infants, particularly younger than 1 year old, have higher intrinsic vagal tone than older children or adults. Atropine serves as a vagolytic and can reduce the risk of bradycardia resulting from laryngoscopy in this age group. There is an association between the use of succinylcholine and bradycardia. Data suggest that this risk may be tied to use with selected inhaled anesthetics (eg, halothane) and with newer induction agents the incidence of succinylcholine-related bradycardia is very low. Given the limited available evidence, routine use of atropine for patients receiving succinylcholine during RSI is not necessary. Atropine may be helpful for bradycardia that exists prior to the procedure, but it should not be administered until attempts are made to appropriately oxygenate the patient.

Data on the effectiveness of lidocaine in blunting the sympathetic response to laryngoscopy in patients with suspected elevated ICP is limited to case series and extrapolated from adult experience. Literature reviews have failed to identify a benefit in adult head injured patients, and no supporting data exist in pediatric...

populations. Therefore, we do not recommend the routine use of lidocaine.

Sedatives

Sedatives rapidly induce unconsciousness and facilitate intubation. Providers should choose sedatives based on their efficacy and adverse effect profile and matched to the clinical situation. In particular, providers should pay careful attention to the hemodynamic profile of these agents, to minimize the risk of clinical deterioration during RSI.

Etomidate is a common sedative used for pediatric RSI. It has reliable efficacy and pharmacokinetics and a stable hemodynamic profile. Etomidate may suppress adrenal corticosteroid synthesis. However, no convincing data exist to suggest that administration of a single dose during intubation influences clinical outcome. Pediatric advanced life support (PALS) guidelines have included precautions against “routine use” in septic shock and suggest consideration of stress dose hydrocortisone when etomidate is used.

Ketamine is a dissociative anesthetic with reliable and rapid onset, which is used frequently for procedural sedation and analgesia in pediatrics. It causes the endogenous release of catecholamines, making it appealing for patients with hypotension or shock. Adverse reactions to ketamine include vomiting, laryngospasm, myoclonus, and emergence phenomenon. Although ketamine is a known sialogogue, the co-administration of atropine is unlikely to be of help during RSI given that the onset of action for the drying effects of atropine may take up to 20 minutes. Ketamine has been shown to increase ICP, although the significance of this on clinical outcome is unclear. Controversy continues to exist as to whether head trauma and concern for increased ICP should be a relative contraindication to its use.6-8 The catecholamine release may lead to beta-agonist effects resulting in bronchodilation, making it an ideal drug for patients with bronchoconstriction. This same benefit may not apply in conditions such as bronchiolitis, in which airway edema and debris are the primary etiology of airway obstruction. Ketamine is considered the sedative of choice for children in septic shock requiring RSI because of its ability to maintain mean arterial pressure.

Propofol has rapid and profound sedative properties, that when combined with its short duration of action, makes it an ideal induction agent. However, as a vasodilator and myocardial depressant, it should be used with caution in any patient with tenuous hemodynamics, including hypovolemia or shock. It may also
Neuromuscular Blocking Agents

The purpose of using a neuromuscular blocking agent (NMBA) is to relax airway musculature and to block airway protective reflexes during laryngoscopy and facilitate the passage of the ETT. The aim is rapid onset of action to limit the time without spontaneous or assisted ventilation. Succinylcholine and rocuronium are the most commonly used NMBA for emergent pediatric RSI. Understanding the specific benefits and risks of each is helpful in creating an airway management plan.

Succinylcholine has a rapid onset of action of 30 to 60 seconds and duration of action of 3 to 8 minutes. It is the oldest and often the most familiar NMBA for emergency clinicians and has a long track record of safe and effective use. Higher doses (2 mg/kg) are recommended in neonates and infants compared to 1.5 mg/kg for older children. Providers should be aware of several side effects and potential risks that exist with its use. Muscle fasciculations result from the depolarizing effect of this agent, although young children may not have large enough muscle mass for this to result in clinically observable effects. Use of succinylcholine can result in hyperkalemia, which can be fatal in a number of clinical conditions (see Table 161.2). In many patients, these diagnoses are known or suspected; however, published case series have described use in infants with undiagnosed myopathies leading to hyperkalemia arrest. As a result, an U.S. Food and Drug Administration (FDA) Black Box warning exists for the use of succinylcholine in children, although given the rarity of these conditions, exception has been allowed for emergency use. Given this waiver, succinylcholine is still the most commonly used NMBA in pediatric emergency airway management. Other serious but rare adverse effects of succinylcholine use in children include masseter spasm and malignant hyperthermia, which are most commonly associated with halothane use.

Rocuronium is the most common nondepolarizing NMBA used in emergency airway management in children. Pediatric data suggest that rocuronium at a dose of 1.2 mg/kg has equivalent efficacy in time to intubation conditions as succinylcholine. The duration of action, however, is much longer with a time to return of spontaneous respirations of anywhere from 20 to 90 minutes. The primary advantage of nondepolarizing agents is the absence of the risks (eg, hyperkalemia) associated with depolarizing agents. The longer duration of action can be of concern if the airway cannot be secured or in patients in whom rapid return of examination findings (eg, neurological examination) is important. However, it may also have advantages if subsequent management may include imaging, additional vascular access, initial ventilator management, or other procedures. A reversal agent for rocuronium exists that can limit its duration of action to less than that of succinylcholine; however, it was only recently licensed for use in North America therefore clinical experience is limited.

Basic Airway Management

The priority in pediatric airway management is establishing effective oxygenation and ventilation. For children with hypoxemia but effective ventilation and without concern for increased work of breathing, passive supplemental oxygen delivery can be sufficient. For mild hypoxemia in children who will not tolerate a nasal cannula or facemask, “blow-by” oxygen using a mask, shovel, or a cupped hand or plastic funnel attached to oxygen tubing aimed toward the face are options. Nasal cannula can provide more consistent oxygen delivery, particularly in infants who are preferential nasal breathers. Simple facemasks can be used, whereas non-rebreather masks provide maximal passive oxygen delivery in spontaneously breathing patients.

When ventilation is of concern or a child’s work of breathing is excessive, assisted ventilation may be required with a bag and mask. Effective assisted ventilation requires: (1) a patent airway and (2) an effective mask seal. Opening the airway is accomplished with positioning of the child, avoiding flexion of the neck from a large occiput or from downward pressure on the face when applying the mask. Application of basic airway maneuvers including a head tilt–chin lift maneuver or a jaw thrust can be of further help. Nasopharyngeal and oral airways can be of value when the airway is being partially or completely obstructed, often by the tongue or soft palate. Oral airways will only be tolerated in patients with depressed mental status, either pharmacologically induced or related to underlying pathophysiology. To create an effective mask seal, the provider first needs to select the appropriate size mask. An ideal fitting mask is large enough to cover the nose and open mouth but should not allow air leak across the bridge of the nose or off the base of the chin. Breaths should deliver an appropriate volume and pressure. There may be a tendency in an acute situation to deliver a much larger tidal volume than is appropriate for the size of the child, which may result in barotrauma. Gentle rise of the chest accompanied by clinical improvement are key clinical features of effective assisted BMV. The bag-mask device should be squeezed just until chest rise is initiated and then released. The emergency clinician may time ventilation by stating “squeeze, release,” which slows ventilation rate and may reduce complications from hyperventilation and gastric insufflation during rescue ventilation. Cricoid pressure has little utility and should be used with caution in children. Too much cricoid pressure can compress the pliable pediatric trachea, leading to iatrogenic upper airway obstruction. Cricoid pressure should be lightened or released if felt to impede BMV.

Advanced Airway Management

Chapter 1 covers a detailed approach to RSI. The general approach to the procedure is identical to that of an adult, although there are several pediatric considerations worthy of mention.

Preparation

Passive oxygen delivery devices, self-inflating bags and masks, oral and nasal airways, laryngoscope blades, ETTs, stylets, and rescue devices all come in varying sizes to match the anatomy of the child. Generally having at least two sizes of ETTs (estimated size and a half size smaller) available during the procedure is prudent. Having a systemic approach to identifying the correct equipment prior to initiating the procedure can eliminate errors and failed attempts in critical situations. Potential resources include a length based resuscitation system (see Fig. 161.2), pediatric resuscitation cards, print or online textbooks, or mobile device applications.

Preoxygenation

As described earlier, young children desaturate much more quickly than adolescents or adults. In a patient with sufficient respiratory effort, preoxygenation with maximal passive oxygen delivery (ie,
a non-rebreather mask) for 2 to 3 minutes may be sufficient in healthy children. However, patients requiring emergency intubation often have compromised pulmonary function or respiratory effort and may benefit from a more prolonged preoxygen delivery time. A technique of using vital capacity breaths for more rapid preoxygenation will be difficult to accomplish in children who may not be cooperative with this technique. Even with appropriate preoxygenation, a significant percentage of young children will desaturate during intubation attempts, particularly those with underlying respiratory illness or when intubation attempts are prolonged (Fig. 161.4). Due to children’s propensity to quickly drop oxygen saturations during intubation attempts, we recommend high flow nasal cannula oxygenation be performed during RSI. As a simplified approach in infants and children, we recommend 5 L/min for infants and 15 L/min for older children to prevent the drop in oxygen saturation during the apneic period of RSI. Positive pressure ventilation with bag-mask device should be considered at the first sign of desaturation, and absolutely initiated when oxygen saturation drops below 95%. Once oxygen saturation has improved, additional attempts can begin.

Positioning

As described earlier, age-appropriate positioning is required during laryngoscopy and endotracheal intubation. Alignment of the oral, pharyngeal, and tracheal axes greatly facilitates visualization. In neonates and infants, a shoulder roll is required, in toddlers and school age children, no roll is necessary; adolescents will often require elevation of the head similar to adults.

Placement of Tube

When performing direct laryngoscopy, straight blades are preferred in infants and younger children in whom the epiglottis is often larger and more likely to fall into the line of sight. In addition, young children may not have a well-developed hyoepiglottic ligament, which will inhibit elevation when a curved blade is placed in the vallecula. In younger children, there is a tendency to insert the laryngoscope blade too deeply, resulting in retroglottic or esophageal placement. With this in mind, emergency clinicians should start the intubation procedure by placing the laryngoscope blade just to the base of the tongue and lift up to view the airway anatomy. Identify structures from the mouth down, first directly identifying the base of the tongue and the epiglottis prior to insertion of the straight blade underneath the epiglottis to visualize the vocal cords. If no laryngeal structures are identified due to deep insertion, the blade should be slowly withdrawn, and the cords or the epiglottis will often fall into view.

Given the superior position of the larynx in children, use of a stylet is often helpful in guiding the ETT into the glottic opening. Given the relatively small size of the oropharyngeal cavity, the tube should be placed from the 3 o’clock position, often with an assistant applying lateral traction to the child’s lip to provide more room for tube insertion.

There is a tendency to insert the ETT too far in the very young child in whom the distance from laryngeal cords to tracheal carina may just be a few centimeters. Right mainstem intubation is difficult to appreciate on auscultation, particularly in the infant whose breath sounds may be transmitted throughout the chest. Using a pediatric resuscitation resource as described earlier, or the formula (tube size × 3 = depth [cm] at the lip) can approximate insertion depth. Under direct visualization, the vocal cord markers on the tube should rest just below the glottic opening, or the cuff observed to pass just beyond the vocal cords.

Post-Intubation Management

Optimally, the ETT should be visualized to pass into the glottic opening. If vocal cords are not seen, passage of the tube below the epiglottis and above the posterior cartilages may indicate successful ETT placement but must be confirmed with clinical assessment in conjunction with other confirmatory tests. Visible chest wall rise, auscultation of breaths sounds in both axillae, absence of gurgling noise in the epigasium (ie, absence of esophageal placement), and improving oxygenation are all used to confirm tube position. However, end-tidal carbon dioxide (ETCO₂) detection, either with a colorimetric device or capnography, is the most reliable and accurate measure of correct tube placement.

Pediatric colorimetric ETCO₂ detectors are available for children weighing less than 15 kg in whom smaller tidal volumes may result in less apparent detection using adult-sized devices. Detection of ETCO₂ confirms the ETT is in the tracheobronchial tree; however, it does not preclude a right mainstem intubation. In patients in cardiac arrest, gas exchange in the lungs is markedly reduced, and CO₂ may not be detectable. Here, an esophageal detector device or bulb may be used to confirm tracheal placement in children who weigh more than 20 kg. Point-of-care ultrasound has been piloted as a real time modality for detecting bilateral lung sliding or diaphragm excursion. However, a chest radiograph is still considered standard of care to confirm appropriate depth. Even small movements of the child’s head can result in accidental displacement of the tube. Flexion of the neck advances the tube into a mainstem bronchus, whereas neck extension can lead to unintended extubation. After intubation, the ETT should be secured and, as is possible, the child’s head and neck kept still.

Most sedatives used for induction will wear off before rocuronium; therefore post-intubation sedatives should be administered after the airway has been secured. Table 161.3 lists common drugs used for post-intubation sedation in the pediatric population. Decisions regarding continued neuromuscular blockade can be made based on clinical context, including desire for return of clinical examination, ventilation management strategies, need for additional procedures or diagnostics studies, and need for interfacility transfer.
**Video Laryngoscopy**

Video laryngoscopy is emerging as an approach to pediatric airway management. Much as in adults, data support improved laryngeal views with video laryngoscopes, with particular benefit in cases where there is difficulty visualizing the vocal cords or Cormick and Lehan grade 3 or 4 airways. In addition, video laryngoscopy allows for shared viewing by multiple providers, which permits real-time guidance and supervision during tracheal intubation. Currently, data on the use of video laryngoscopy in pediatric patients is limited to the anesthesia literature or performance in simulated scenarios. Although video laryngoscopy improves visualization, procedural performance metrics are not improved with its use. However, video laryngoscopy has been shown to have a faster learning curve than direct laryngoscopy. This may be particularly important for airway management in children, given the infrequency with which pediatric airway management is performed in the ED.

There are a number of video laryngoscopes available for use in pediatrics. Many are smaller adult models, which permit use in older children. Currently, only a few devices are available with a complete range of sizes that allow for use across all pediatric ages, from neonates through to adolescents. There are unique advantages, potential drawbacks, and subtleties in technique for using each (Table 161.4). The decision regarding which device to use is ultimately based on availability, operator preference, operator experience, and patient-specific attributes that may favor a given approach.

**Airway Rescue Devices for Children**

The overall success rate for advanced airway management in children is more than 99%. Therefore, the need for rescue device use is fortunately rare. Nonetheless, it is imperative to have a contingency plan for circumstances in which a provider cannot secure the airway. In most circumstances, effective BMV will be the mainstay for establishing adequate oxygenation and ventilation until additional personnel and resources are available to reattempt a definitive airway. Alternative strategies to manage the airway when intubation cannot be accomplished using traditional techniques include supraglottic devices (SGDs) or optical approaches to improve glottic visualization.

SGDs have been demonstrated to be a reliable way to establish oxygenation and gas exchange in the normal and difficult pediatric airway, as well as during resuscitation. First generation devices have been used in anesthesia for more than 30 years, whereas second generation devices also include a gastric channel to allow gastric decompression. In addition to the gastric channel, newer versions of SGDs have alternative construction that may be advantageous in pediatrics. For example, the air-Q does not have aperture bars and uses a shorter wider tube to allow passage of an ETT through the lumen. The I-gel uses a thermoplastic elastomer that molds to the airway as it warms from body temperature. This allows a tighter seal and avoids complications related to cuff hyperinflation.

In most cases, SGDs are easily and rapidly placed, with more than 90% success rate on first attempts; devices sized for neonates and young infants are the most difficult to place. Placement technique is similar to adults with two potential differences: (1) some studies have demonstrated improved placement success and fewer complications when using a rotational approach with traditional laryngeal mask airways (LMAs), and (2) insertion of the SGA with the cuff partially inflated may facilitate placement and help it mold to the shape of the pharynx.

Pharyngeal sealers, also called esophageal blockers, are double-balloon devices in which the tip is placed into the upper esophagus, and ventilation occurs between one balloon occluding the proximal esophagus and another occluding the airway above the glottis. The two most noted are the Combitube, which is available for use in children greater than 48 inches tall, and the laryngeal tube, which comes in a full range of pediatric sizes. Data regarding use in emergent pediatric airway management are limited. Given the entire spectrum of pediatric sizes and the ease of insertion and use, we recommend the laryngeal tubes for use in children.

A number of pediatric devices beyond video laryngoscopes are available to facilitate visualization and intubation in cases of difficult airways. Flexible fiberoptic scopes can be effective, although extensive experience is required. This approach is most commonly used by anesthesia or otorhinolaryngology, often in the operating room. Similarly, fiberoptic styles are available in pediatric sizes to facilitate visualization with intubation. As with video laryngoscopes, gaining experience with the technique for a given device prior to use in the stressful scenario of a difficult or failed airway is critical.

**Pediatric Surgical Airway Techniques**

In the rare case of the “can’t intubate, can’t ventilate” child, a surgical airway represents the final airway option. This can occur if direct laryngoscopy/video laryngoscopy has failed and the emergency clinician is unable to maintain oxygenation and ventilation.

Every year of age, or to the adaptor from a 3.0 \text{ ENK modulator}, Cook Inc.) with oxygen flow set at 1 L/min for every year of age, or to the adaptor from a 3.0 mm ETT, which is then connected to a standard bag-mask device. This technique is preferred to true “jet” ventilation, which uses a much higher-pressure oxygen source and has a greater potential for iatrogenic injury. Open surgical cricothyrotomy, performed in the same way as in an adult, is reserved for children for which anatomical landmarks can be found and in whom the cricothyroid membrane is larger. The literature does not support a specific age cutoff for needle cricothyrotomy versus surgical cricothyrotomy, but needle cricothyrotomy should be performed when indicated in infants and small children (<6 years of age or older depending on anatomical landmarks).

**OUTCOMES**

The majority of pediatric intubations performed in the ED are successful. Despite the relative rarity of the procedure, there is significant overlap in the techniques and strategies used in adult airway management. There are a limited number of anatomic and physiologic differences that can be learned and mastered. The cognitive burden associated with the procedure can be overcome by length/sized based systems to allow the clinician to focus on the critical actions necessary to successfully manage the airway.

**KEY CONCEPTS**

- Pediatric airway management is a relatively rare skill to perform in most emergency departments (EDs), and skill maintenance is difficult based solely on clinical practice.
- There are several anatomic differences that impact pediatric airway management, and these occur mostly in the very young child (<2 years old). Small infants have a large occiput and a high, anterior airway, which impacts positioning during intubation. They have a small, underdeveloped cricothyroid membrane, making needle cricothyrotomy the procedure of choice for surgical rescue of the failed airway. They are also more dependent on diaphragmatic excursion for ventilation, thus gastric insufflation can result in difficulty with providing rescue ventilation.
- Children are prone to desaturation due to their high metabolic rate and small functional residual capacity, making preoxygenation and maintenance of oxygenation during intubation crucial.
- The cognitive burden inherent in dealing with the large age/size spectrum in pediatrics can be overcome with reference aids that organize equipment selection and drug dosing based on length/age/size. Formulas have been developed to aid in selection of the correct endotracheal tube (ETT) size and determine appropriate depth of ETT.
insertion. For estimation of uncuffed tube sizes in children older than 1 year old: ETT size = 4 + (age in years/4). Subtract 0.5 in size for cuffed tubes. To estimate the depth of ETT insertion (the so-called “lip to tip” distance), multiply the ETT size \( \times 3 \) (eg, a 5.0 ETT would be inserted to 15 cm at the lip).

- Rapid sequence intubation (RSI) is the preferred method of airway management in the vast majority of pediatric cases in the ED.
- Compared to adults, children are more prone to desaturation over the time it takes for a neuromuscular blocking agent (NMBA) to take effect. Use of high-flow nasal cannula during the apneic period of RSI has not been well studied in children, but we recommend its use at 5 L/min for infants and 15 L/min for children and adolescents. Assisted ventilation (coordinated with the child’s respiratory efforts) should only be used if oxygen saturation drops below 95%.
- Video laryngoscopy is an evolving technology for use in pediatrics and assists in visualization of the airway but prolongs time to intubation.
- Surgical airway techniques differ in infants and young children, necessitating a needle technique that is different from the older child or adult. This technique provides a mechanism to oxygenate the “can’t intubate, can’t ventilate” child, but should not be relied on as a definitive airway.

**KEY CONCEPTS—cont’d**

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
161.1. Which of the following is a correct formula?
A. Cuffed ETT size (1 to 10 years old) = 4 + (age in years/2)
B. ETT depth = 3 × ETT size
C. Cuffed ETT size = 4 × ETT size
D. Uncuffed ETT size (1 to 10 years old) = (16/age in years) + 4

Answer: B. Correct formulas are as follows:
Uncuffed ETT size = 4 + (age in years/4)
Uncuffed ETT size = 3.5 + (age in years/4) (or subtract 0.5 from the formula for uncuffed tubes)
ETT depth = 3 × uncuffed tube size

161.2. Which of the following should be used for proper positioning of the pediatric patient during endotracheal intubation?
A. The chin should be tilted and the head lifted.
B. The infant younger than 6 months old should have a towel role placed under his occiput to align the airway axes.
C. The neck should be placed in slight flexion and the shoulders extended.
D. The patient should be positioned so that a line drawn through the external auditory canal and the anterior shoulder is parallel to the bed.

Answer: D. The relatively large head and occiput of the infant results in slight flexion at the neck when supine, impeding the ability to visualize the glottis. The infant is correctly positioned so that a line drawn through the external auditory canal and the anterior shoulder is horizontal and parallel to the bed. In the infant (<6 months old), this is accomplished by placing a towel roll under the patients shoulders, elevating the body and overcoming the flexion associated with their large occiput. A head tilt–chin lift may open the airway.

161.3. Relative to rapid sequence intubation (RSI) in adults, children undergoing RSI:
A. Are less affected by stomach pressures
B. Are more likely to develop bradycardia in response to hypoxia
C. Have less missed intubations
D. Have less pliable airways
E. Maintain their oxygen saturations longer after paralytics are administered

Answer: B. Children have a higher metabolic rate and thus a higher oxygen demand. In the absence of respiratory support, children will drop their oxygen saturations more quickly than adults due to their relatively greater consumption of oxygen. The more pliable pediatric thorax combined with children’s lower ventilatory reserve make stomach inflation a significant impediment to effective respiratory support. Pediatric intubations are infrequent and multiple pediatric intubation attempts are more common in children than in adults.

161.4. Which of the following does not characterize the pediatric airway relative to adults?
A. A straight blade is used to pick up the floppy epiglottis.
B. Infants may require a shoulder roll to align airway axes.
C. The airway is more pliable.
D. The airway is more superior and posterior.
E. The epiglottis is larger and omega-shaped.

Answer: D. Small infants have a large occiput and a high, anterior airway, which impacts positioning during intubation, often requiring a shoulder roll to align airway axes. The airway is also more pliable and the membranes thinner, necessitating needle cricothyroidotomy for surgical airways in children younger than 10 years old. Blade choice is age-dependent, and a straight blade is recommended in young children; this blade lifts the relatively larger epiglottis to visualize the vocal cords.

161.5. Following the administration of succinylcholine in a 7-year-old boy with respiratory distress, severe masester spasm is noted. Which of the following medications should be administered to terminate this spasm?
A. Diazepam
B. Fentanyl
C. Repeated dose of succinylcholine
D. Rocuronium
E. Thiopental

Answer: D. Small infants have a large occiput and a high, anterior airway, which impacts positioning during intubation, often requiring a shoulder roll to align airway axes. The airway is also more pliable and the membranes thinner, necessitating needle cricothyroidotomy for surgical airways in children younger than 10 years old. Blade choice is age-dependent, and a straight blade is recommended in young children; this blade lifts the relatively larger epiglottis to visualize the vocal cords.
Answer: D. Masseter muscle spasm is a rare side effect of succinylcholine administration. It primarily occurs in pediatric patients and is typically terminated by the administration of a competitive neuromuscular blocking agent (NMBA), such as rocuronium, vecuronium, or pancuronium. Failure to respond to such therapy should prompt consideration of malignant hyperthermia.
Sedation is a controlled reduction of environmental awareness. Sedation is a continuum that begins with minimal, next moderate, then deep sedation and proceeds to general anesthesia.

Definitions

- Anxiolysis is a state of decreased apprehension concerning a particular situation in which the patient’s level of awareness does not change.
- Analgesia refers to the relief of pain without the intentional alteration of mental status, such as occurs in sedation. An altered mental state may be a secondary effect of the medications administered for this purpose.
- Dissociation is a trancelike cataleptic state induced by an agent such as ketamine and characterized by a profound analgesia and amnesia. Protective reflexes, spontaneous respirations, and cardiopulmonary stability are retained.
- Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive functions and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
- Moderate sedation/analgesia (formerly called “conscious sedation”) refers to a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Reflex withdrawal from the painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is always maintained.
- Dissociative sedation is a trancelike cataleptic state induced by the dissociative agent ketamine and characterized by profound analgesia and amnesia, while protective airway reflexes, spontaneous respirations, and cardiopulmonary stability are maintained.
- Deep sedation/analgesia describes a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous stimulation may be inadequate. Cardiovascular function is usually maintained.
- General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even with painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

- Procedural sedation and analgesia (PSA) is a technique of administering a sedative or dissociative agent, usually along with an analgesic, to induce a state that allows the patient to tolerate unpleasant procedures while maintaining adequate spontaneous cardiorespiratory function. It is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously.

The goal of PSA is to alleviate the anxiety, pain, and suffering associated with medical procedures. PSA is an essential part of emergency medicine practice and part of the core curriculum for emergency medicine training programs. Providers should be prepared to intubate if sedation becomes deeper than expected. In the event the patient requires ventilatory support during PSA, providers should determine the patient’s American Society of Anesthesiology (ASA) physical status classification (Table 162.1) and Mallampati score (see Chapter 1) to identify potential difficulties.

At least one provider, usually a nurse, should be available to document and monitor the patient. Depth of sedation, heart rate, blood pressure, pulse oximetry, and capnography readings should be recorded at regular intervals. Although there are scales for assessing the depth of sedation in pediatric patients, continuous monitoring is more important than any specific measurement on a sedation scale. We recommend continuous cardiac rhythm monitoring, especially for high-risk patients (eg, preexisting cardiovascular disease or a history of dysrhythmias) or high-risk procedures (eg, cardioversion) because it has been useful in those with a cardiac history and older patients; although there is no evidence of benefit in young healthy individuals.

Providers administering procedural sedation should have training and skills in airway management. In addition to monitoring equipment and oxygen, age-appropriate suction, bag-valve-mask, and intubating equipment should be available and readied prior to administering medications. The SOAP-ME mnemonic provides an equipment checklist for pediatric sedation:

- Size-appropriate suction catheters
- Oxygen supply
- Airway: Size-appropriate airway equipment
- Pharmacy: Advanced life support medications and antagonists
- Monitors: Size-appropriate oximeter
- Equipment or drugs for a particular case

Once the procedure is complete and the painful stimuli are removed, patients are at risk of hyperventilation or hypoxia. Monitoring should continue until the patient has met predetermined discharge criteria, which should include normal vital signs and baseline mental and physical status. Once fully awake, patients
should be discharged to the care of a responsible adult. Patients should receive predeveloped age-appropriate PSA discharge instructions.

**MANAGEMENT**

Table 162.2 details specific PSA sedative agents commonly used in infants and children. Patient age, preexisting conditions, and anticipated level of pain or anxiety should guide choice of sedative. Providers should administer drugs by slow intravenous (IV) titration to decrease the risk of adverse events, including hypotension and respiratory depression.

**Preprocedural Fasting**

The ASA has guidelines for preoperative fasting in healthy patients of all ages undergoing elective procedures. In patients undergoing PSA in the emergency department (ED), the evidence indicates that preprocedural fasting does not decrease the risk of emesis or aspiration as noted in the American College of Emergency Physicians (ACEP) clinical policy. Therefore, adherence to the ASA preoperative fasting guidelines for procedures is not necessary in ED patients undergoing PSA.

**Supplemental Oxygen and Capnography During PSA**

Although supplemental oxygen does prevent hypoxemia in some patients, it may delay the recognition of hypoventilation or apnea and, therefore, should be available but not placed routinely. Hypoventilation, however, should be detected prior to any drop in pulse oximetry, irrespective of use of supplemental oxygen. We are in agreement with recent ACEP clinical policy recommendations that capnography should be routinely used to monitor ventilation in children undergoing PSA.

**Monitoring**

Bispectral monitoring is a technology used during anesthesia that takes several electroencephalographic parameters and calculates a number from 0 to 100, which gives an indication of a patient’s depth of anesthesia, with a bispectral index (BIS) between 40 to 60 appropriate for general anesthesia. The BIS does not correlate with the level of consciousness per se, but rather the effect of the drug on the cerebral cortex. The BIS is unreliable in infants with immature electroencephalogram (EEG) patterns, because the BIS was developed using adult EEG patterns. Although bispectral monitoring has been shown useful for monitoring the level of awareness in patients undergoing general anesthesia, its usefulness is yet unproven for differentiating levels of sedation (mild, moderate, or deep) during ED PSA.

**Specific Medications**

**Propofol**

Propofol has several advantages for PSA; it has a rapid onset, is short acting, and has antiemetic properties. Its side effects include hypotension and respiratory depression, leading some to recommend limiting its use to the operating room. However, a large, prospective multicenter observational study found that propofol can be used safely and effectively in settings outside of the operating room, including the ED. Although the dosing of propofol varies from 0.5 to 1.5 or even up to 2 mg/kg, an initial dose of 0.5 to 1.0 mg/kg should be administered and titrated to effect with additional doses, usually in increments of 0.5 mg/kg.

**Ketamine**

Ketamine, a dissociative anesthetic, has sedative, amnesic, and analgesic properties. Ketamine maintains cardiovascular and respiratory stability, has minimal respiratory depression, and maintains protective airway reflexes in patients with spontaneous respirations. Ketamine’s sympathomimetic effects include increased blood pressure, heart rate, cardiac output, myocardial oxygen consumption, and bronchodilation, making it the preferred sedative in patients with severe asthma exacerbations.

Apnea is rare with ketamine (0.8% incidence), but has been associated with very high doses, rapid administration, and co-administration with respiratory depressants. Laryngospasm is also rare (0.3% incidence) and has been associated with high doses of the drug. Laryngospasm is usually transient and responds to repositioning of the head, supplemental oxygen administration, and positive pressure ventilation with a bag-valve mask. Although rarely needed, the use of a paralytic at lower doses than required for intubation (eg, succinylcholine given at 10% of a paralytic dose) has been shown to break laryngospasm when the above measures fail. Rapid sequence intubation is rarely needed, but a last resort option to treat laryngospasm.

Ketamine may be given intravenously, intramuscularly, or per os (by mouth). For IV administration in pediatric patients, initial doses range from 1.0 to 2.0 mg/kg, with further bolus doses of 0.5 to 1 mg/kg titrated to desired effect. Intramuscular (IM) dosing is an option when IV access is unobtainable; dosing ranges from 4 to 5 mg/kg. The disadvantages of 1M ketamine include a higher rate of vomiting, longer recovery time, and lack of IV access in the event of complications requiring IV medication administration (eg, paralytics). Ketamine can be given PO at a dose of 5–7 mg/kg, although PO is associated with an increased incidence of side effects, less predictable effect, and longer duration (up to 1 hour).

**Use of Ketamine in Head Injury Patients.** Studies from the 1970s on use of ketamine for rapid sequence intubation in surgical and neurologic patients, many of which had cerebrospinal fluid outlet obstruction, suggested that ketamine can increase intracranial pressure (ICP). However, since then, multiple studies have dispelled this association. A meta-analysis of randomized clinical trials found that ketamine does not increase ICP and therefore it can be used in patients with head trauma.

---

*Doses will vary with the individual patient; these are some generally recommended starting doses. Some patients will need greater than the typical maximum dose, whereas others may be sedated with less than the usual dose. So it is best to titrate the dose in all patients.*

*Be especially cautious in at-risk patients. At-risk patients include those patients with significant heart disease, including heart failure or pulmonary hypertension, liver disease, renal failure, and patients at the extremes of age (infants, particularly neonates and the geriatric patient). It may be prudent in these patients, to “start low and go slow.”*  

*Other agents used for sedation, eg, DPT (meperidine [Demerol], promethazine [Phenergan], and chlorpromazine [Thorazine]) IM should be avoided because there are better, newer agents for sedation with fewer side effects. Chloral hydrate has been used in the past but is used infrequently at present because there are other better options.*

*Ketamine’s effect on ICP is discussed in the text. Previously ketamine was thought to be contraindicated if there was an increase in ICP. However, recently, this concept has been challenged. If ketamine is given PO or PR, higher doses are needed with less predictable effect and increased side effects so PO and PR routes are not recommended.*

*Midazolam may be given by several routes including IV, IM, IN, PO, and PR. The PO and especially PR routes of administration have more variable absorption and effects, so they are not commonly used.*

*Methohexital can be given IM and PR with longer onset and duration and more variable effect, so these routes of administration are less commonly used.*

*Pentobarbital can be given PO or PR, but onset and duration are longer with more variable effect; so IV is preferred.*

*BP: Blood pressure; CAD: coronary artery disease; CBF: cerebral blood flow; CV: cardiovascular; EDTA: ethylenediaminetetraacetic acid; HR: heart rate; ICP: intracerebral pressure; IM: intramuscular; IN: intranasal; IOP: intraocular pressure; IV: intravenous; LV: left ventricular; PO, per os (by mouth); PR, per rectum; PSA, procedural sedation and analgesia; RSI, rapid sequence intubation.*
Recovery Agitation: Use of Benzodiazepines. Emergence reaction or recovery agitation refers to agitation (which may include hallucinations or delirium) that can occur after waking up or emerging from ketamine. In a large meta-analysis of pediatric ketamine sedations, the incidence of any recovery agitation was 7.4% and clinically important recovery agitation was 1.4% and was not significantly associated with age. Emergence reactions occur more frequently in adolescents, adults, females, and individuals with psychiatric disorders, and can be treated with midazolam (0.03 mg/kg) up to a maximum of 6 mg for ages 6 months to 5 years old, 10 mg for children 6 years old and older and adults. 

The routine use of midazolam in adult patients receiving IV or IM ketamine was recently found to decrease the absolute risk of emergence reactions by 17%, with a number needed to treat of 6. However, pediatric studies have not demonstrated the benefits with its routine use, likely due to midazolam’s own adverse effects; although rare, midazolam can itself cause paradoxical agitation. As no pediatric studies to date have shown benefit, we do not recommend that midazolam be routinely given as an adjunct to ketamine in children. Providers should consider an alternate agent or ketamine plus midazolam for older teens and children with psychiatric illness.

Use of Anticholinergics. Ketamine stimulates tracheobronchial and salivary secretions. Except in young infants (eg, age younger than 3 months old due to age-related differences in airway anatomy/reactivity and laryngeal excitability) routine use of anticholinergics is probably not necessary. Providers may consider anticholinergics for children undergoing an airway examination (eg, fiberoptic laryngoscopy) to improve visibility, or in patients with clinically significant hypersalivation or an impaired ability to mobilize secretions.

Glycopyrrolate is the preferred anticholinergic over atropine; it is a more potent anti-sialogogue and has fewer tachy-dysrhythmias. Unlike atropine, glycopyrrolate does not cross the blood brain barrier, so it has no central nervous system (CNS) side effects. CNS side effects of atropine range from drowsiness and coma and include headache, nervousness, insomnia, excitement, dizziness, disorientation, hallucinations, and ataxia. Headache is the only CNS side effect listed for glycopyrrolate.

Use of Antiemetics. The incidence of any vomiting with ketamine sedation is 8.4%. It usually develops during recovery when patients are alert and can clear their airways. Risk is higher among adolescents and patients receiving high doses or IM administration. Although ondansetron is associated with a small decrease in the incidence of vomiting associated with ketamine sedation in children, ondansetron is associated with other adverse effects, including QT prolongation and serotonin syndrome. We recommend reserving treatment with ondansetron for patients who develop nausea and vomiting during recovery from ketamine.

Ketofol: Ketamine Plus Propofol

The combination of ketamine with propofol has the potential to provide benefits of both sedatives. The combination allows for lower doses of each medication, which may theoretically minimize adverse effects of either sedative alone. For example, the cardio-respiratory stimulatory effects of ketamine could offset the dose-related respiratory depression and hypotension from propofol. However, ketofol has not been shown to have fewer airway complications or incidences of respiratory depression than either sedative alone.

Ketamine and propofol (ketofol) can be dosed at 0.50 mg/kg to 0.75 mg/kg for each drug. Ketofol can be administered via a 1:1 single–syringe mixture of 10 mg/mL of ketamine and 10 mg/mL of propofol (eg, 2 mL for a 20 kg child is equivalent to 0.50 mg/kg of each drug). For short procedures, re-dosing is usually not needed. For longer procedures, if the sedation is wearing off, then propofol is usually redosed (at a dose of 0.1 to 0.5 mg/kg IV) because of its shorter half-life.

OUTCOMES

Adequately treating the anxiety and pain that can occur with medical procedures results in greater procedural success rates, improved patient and caregiver satisfaction, decreased likelihood of the patient developing chronic pain, and improved patient outcomes. Patients at increased risk of adverse events during PSA include the following: the very young or very old, those with comorbidities (eg, cardiopulmonary diseases) or craniofacial abnormalities (eg, Down syndrome and Pierre Robin syndrome), the morbidly obese, and those with a higher ASA physical status classification (see Table 162.1).

PAIN MANAGEMENT

PRINCIPLES

Pain is defined as an unpleasant visceral or somatic experience or sensation associated with actual, potential, or perceived tissue damage. Pain receptors, termed nociceptors, are the free nerve endings of a sensory neuron that convert mechanical, thermal, or chemical stimuli into electrical activity, and initiates an impulse that travels along the neuron and then on to the dorsal horn of the spinal cord (Fig. 162.1). Input from various peripheral nerves and additional sensory stimuli are processed, undergoing integration and modulation in the dorsal horn of the spinal cord, and then transmitted up the spinal cord to the CNS (Fig. 162.2).

There are two types of pain: nociceptive or neuropathic. Nociceptive pain occurs when tissue injury or inflammation stimulates intact pain receptors. Nociceptive pain can be further divided into visceral pain (ie, of internal organs) and somatic pain (ie, of the skin, soft tissue, and musculoskeletal structures). Neuropathic pain occurs when there is abnormal functioning or stimulation of damaged sensory nerves. Children with severe developmental impairment may have central neuropathic pain or pain secondary to visceral hyperalgesia.
Neuropathic pain is typically burning, searing, tingling, shooting, or electric in quality. Nociceptive somatic pain is generally described as sharp and well localized. However, pain in deeper structures (eg, bones, joints, or tendons) can cause achy, diffuse, or radiating pain. Nociceptive visceral pain is typically poorly localized, deep, and aching. Chronic pain is a maladaptive response in which the pain persists after the original injury or illness has resolved.

**MANAGEMENT**

**Pain Assessment**

Patient self-report is the most accurate measure of pain severity. Pain assessments can be used to guide pain management. Pain scales should be age-specific; subjective or self-reporting scales can start being used at 3 years of age, depending on developmental level. Children younger than 3 years old do not have the cognitive or verbal skills needed to communicate levels of pain and, thus, require behavioral or psychological pain scales. Behavioral pain scales rely on the observation of specific child or infant behaviors. Some of the parameters used in behavioral pain scales include facial expressions, consolability, interaction level, limb responses, trunk motor responses, and verbal responses. Behavioral and physiologic pain scales combine behavioral observations and physiologic parameters (eg, vital signs) to obtain a score.

The numeric rating scale (NRS) and the visual analogue scale (VAS) are commonly used self-report scales that have been found to have reliability and validity. With the VAS, patients are asked to place a mark on a 10-cm line with descriptors along the line. With the NRS, patients are asked to rate their pain severity on a scale from 0 to 10 or 0 to 100, with 0 = no pain and 10 or 100 = worst pain possible. Horizontal lines are preferred rather than vertical lines because scores are more normally distributed. Patients with poor hand-eye coordination and visual acuity or hand dexterity, such as the cognitively impaired or geriatric patients, have difficulty completing the VAS (19% to 25% of the elderly fail to use the VAS correctly). Thus, the NRS is more commonly used and is preferred over the VAS.

As noted, the use of pain scales is based on age. Adolescents and adults can rate their pain using a NRS or VAS. Older children (8 to 11 years old) can also use a NRS or VAS. Younger children (3 to 8 years old) can quantify their pain using a faces pain scale, most commonly the Wong-Baker Faces Pain Scale in the United States and the Faces Pain Scale—Revised internationally. The Premature Infant Pain Scale (PIPP) is used to assess pain in premature infants. The Crying, Requires oxygen, Increased vital signs, Expressions, and Sleeplessness (CRIES) Scale is for infants. The Faces, Legs, Activity, Cry, Consolability (FLACC) Pain Scale can be used for infants and toddlers. The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) and the Observational Scale of Behavioral Distress (OSBD) may be used for toddlers and young children.

Nonverbal children with neurological impairment, irrespective of age, cannot self-report their pain. The child’s caregiver generally knows his or her typical behavior patterns, both at baseline and in response to stimuli or needs. Behaviors that may indicate pain include facial expressions (eg, grimacing), vocalizations (crying or moaning), inconsolability, increased movement, increased tone or posture (eg, stiffening or arching), and uncharacteristic or atypical behaviors (eg, withdrawal, lack of expression, or even laughing). The revised FLACC (r-FLACC) scale is one pain scale designed for use in children with cognitive impairment.

**Nonpharmacologic Techniques**

Nonpharmacologic interventions should be used with pharmacologic therapy for pain management. Hypnosis is accepted by the American Medical Association as a medical therapy and has been used to treat anxiety, as well as acute and chronic pain. Children may be more easily hypnotized compared to adults. Studies indicate that hypnosis is efficacious in pediatric patients for painful medical procedures, headaches, sickle cell disease, chronic pain, and even in cancer treatment. Acupuncture and acupressure have been used as a nonpharmacologic method for pain management in non-ED settings.

Techniques that distract from pain should be culturally sensitive and may be low-tech or high-tech. Low-tech distractions include telling stories, reading a book, and playing cards or games. Kaleidoscopes have been successfully used as a distraction in children and adults to decrease the pain of phlebotomy. High-tech distractions involve more expensive electronic equipment, such as handheld computer games or virtual reality. Preliminary research suggests that the high-tech virtual reality that uses multiple sensory inputs may be effective in decreasing pain.

Educated in human growth, development, and psychology, child life specialists are invaluable team members of any pediatric ED. Child life specialists help children effectively cope with illness or injury through play, preparation, and education. A study of children undergoing suturing in the ED found that having a child life specialist use low-tech distractions resulted in fewer fears than in the control group with no distractions.

Perhaps one of the most important and common nonpharmacologic methods for limiting the anxiety and pain of the child or infant is parental presence during the procedure. Techniques used in infants include nonnutritive sucking, breast feeding, skin-to-skin contact (kangaroo care), and sucrose. The use of sucrose water administered by pacifier or oral syringe has been shown to effectively decrease pain in infants 3 months old and younger undergoing painful procedures.
**Topical Anesthetics**

Used in conjunction with other methods for decreasing pain, topical anesthetics may decrease the need for systemic analgesics or local anesthesia. Topical anesthetics can be used for venipuncture, IV cannulation, minor surgical procedures, wound care, suturing, and lumbar puncture. Topical anesthetics are painless to apply and do not distort tissue (eg, for cosmetically important facial lacerations). Needleless, they also avoid the risk of needle sticks.

Different topical anesthetics can be used on intact skin or broken skin (Table 162.3), as well as mucosal surfaces. Vasoconstrictors, such as epinephrine, increase anesthetic efficacy and duration of effect, but generally should not be used where there at an end-arteriolar blood supply (eg, fingertip). Common formulations used for intact skin (eg, prior to venipuncture), are eutectic mixture of local anesthetics (EMLA), liposome encapsulated lidocaine (LMX), and vapo-coolants. Lidocaine, epinephrine, and tetracaine (LET) and tetracaine, adrenaline (epinephrine), and cocaine (TAC) can be used for open wounds. Due to the potential for cocaine toxicity, we recommend using other topical anesthetics instead of TAC. EMLA has been associated with methemoglobinemia, seizures, and respiratory depression with excessive skin application. Methemoglobinemia is associated with the prilocaine component of EMLA and is more likely to occur in patients with glucose-6-phosphate dehydrogenase (G6PD) and those on methemoglobinemia-inducing medications.

The use of topical anesthetic agents (eg, lidocaine and benzocaine) on mucosal surfaces for teething pain or stomatitis has been associated with serious adverse events, including seizures, respiratory depression, cardiovascular toxicity, and death. This has led to a recent black box warning for viscous lidocaine, and the U.S. Food and Drug Administration (FDA) recommendation against using over-the-counter (OTC) topical anesthetics for teething pain. We recommend not using topical anesthetics on mucosal surfaces in infants and young children. For teething pain, use a chilled (not frozen) teething ring or have the caregiver gently massage the gums with a finger. Children with stomatitis can be treated with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs).

The topical vapo-coolants or refrigerant anesthetic sprays have similar uses to topical anesthetics (Table 162.4). Two commonly used vapo-coolants are ethyl chloride, which is flammable, and 1,1,1,3,3 pentafluoropropane/1,1,1,2 tetrafluoroethane, which is nonflammable and ozone friendly. To be effective, application should include correct distance 3 to 7 inches from the skin site, a steady spray covering the specific area (about as large as a quarter for a venipuncture or IV cannulation) and adequate spray time for 4 to 10 seconds or the skin begins to turn white, whichever comes first. Vapo-coolants have also been used to alleviate musculoskeletal pain, muscle pain, and the musculoskeletal injury pain. Vapo-coolants have immediate onset. Although the anesthetic effect subsides within a minute, it can be reapplied.12

The J tip is a needleless jet injector that uses pressurized gas for the delivery of local anesthetic. J tip lidocaine delivery has been found effective in decreasing the pain of peripheral IV catheter insertion. In one study of pediatric ED patients, jet delivered lidocaine was no more effective in reducing pain than jet delivered normal saline; however, both were better than no pretreatment.13 Devices used for injection of local anesthetics are often associated with minor local skin side effects (such as, erythema or bruising) and may produce an audible “pop” when used, which could frighten a young child. One study in pediatric patients found that a cold vibration device placed proximal to the venipuncture site decreased the pain of venipuncture when compared to standard care, which included the use of 4% liposomal lidocaine and vapo coolant.14

**Local Anesthetics**

Local anesthetics reversibly block sodium channels, which inhibits the propagation of nerve impulses (Fig. 162.3). Local anesthetics fall into one of two classes: amides and esters. Amides can be remembered as the prefix before the ending “caine” will have the letter “I” (eg, lidocaine and bupivacaine). Local anesthetics are also classified by duration of action. Local anesthetics that are tightly protein bound to a receptor in the sodium channel (eg, bupivacaine and tetracaine) have a longer duration of action than less tightly bound anesthetics (eg, procaine and prilocaine). Greater concentrations of the local anesthetic will also increase the duration of action.

Potency refers to the degree to which the individual local anesthetic blocks transmission in the neural tissue (Fig. 162.4). The nerve cell membrane consists of a lipoprotein matrix, so local anesthetics that are more lipid soluble (eg, tetracaine) are more potent than less lipid soluble local anesthetics (eg, procaine and prilocaine). Local anesthetics with low lipid solubility must be given in higher concentrations and higher doses to achieve the same efficacy.

When added to a local anesthetic, epinephrine lengthens the duration of the anesthesia, slows systemic absorption, and aids in controlling local bleeding. Clonidine added to a local anesthetic solution (10 μg = 0.1 mL clonidine added to 0.5 mL lidocaine 0.5%) has also been used to increase the duration of anesthesia. Although the risk is currently being questioned, epinephrine-containing local anesthetics should generally be avoided in

</tbody>
</table>

*The dose of EMLA® varies by age and weight, with the maximum amount of intact skin in cm³ over which the cream can be applied and the length of time allowed for skin contact specified.  
*Tetracaine, adrenaline (epinephrine), and cocaine (TAC) is a topical anesthetic used on open dermis, but because of the potential toxicity due to the cocaine component as well as for legal and regulatory issues, it has been replaced by other topical anesthetics.  
*Tetracaine topical (Ametop) has been used in adults and reported in the literature in pediatric patients, but according to Pediatric and Neonatal Lexi-drugs for tetracaine topical under dosing, “Children: safety and efficacy has not been established” so it is not included in this list.  
*Use of topical anesthetic agents on mucosal surfaces in infants and young children, as for teething pain or stomatitis, has been associated with serious adverse events, including seizures, respiratory depression, and death. So they are not included on this list. The American Academy of Pediatrics (AAP) recommends against using topical over-the-counter (OTC) medicines for teething pain. The U.S. Food and Drug Administration (FDA) recommends against using topical over-the-counter (OTC) medicines for teething pain. Such OTC products may contain up to 20% local anesthetic, such as 20% benzocaine, which is 200 mg/mL. This can be compared with the usual concentration of local anesthetics for subdermal injection for suturing, such as 2% lidocaine, which is 20 mg/mL for a tenfold increase to 200 mg/mL for 20% concentration.
EGA, Estimated gestational age.
end-arterial fields (eg, digits) and in patients with vascular pathology (eg, Buerger’s disease, digital vascular injury) who are at high risk for ischemia. Techniques for decreasing injection pain are described in Box 162.1.

The vasoconstrictor reaction is the most common adverse reaction to a local anesthetic. It occurs when an epinephrine-containing local anesthetic is injected into a highly vascular space. The patient suddenly feels a rapid heartbeat and becomes anxious and panicky from rapid absorption of epinephrine. This reaction ends quickly and is not a true allergy.

True immunoglobulin E (IgE)-mediated anaphylaxis to local anesthetics is very rare, especially to the amide class. Reported allergies to amides are more likely to be a reaction to epinephrine or an allergy to one of the preservatives (eg, methylparaben). There is no cross-reactivity between amides and esters, and they contain different preservatives. For patients with a known true allergy to lidocaine, a benzoyl alcohol solution (made by adding 0.2 mL of 1:1000 epinephrine to a 20 mL vial of normal saline containing 0.9% benzoyl alcohol) can be used. Benzoyl alcohol is potent.

*Use of commercially available brand names does not imply endorsement of any medication or product. They are included because individuals may be more familiar with commercial or brand names than the specific drug or category of drugs.

- **Duration** is affected by binding (eg, protein binding produces duration) and concentration (concentration duration). 2% lidocaine has greater duration than 1% lidocaine.
- **Potency** is related to the ability of the local anesthetic to penetrate the lipid membrane of the nerve axon.
- **Highly lipid soluble local anesthetics have greater potency (lipid solubility leads to potency) (eg, tetracaine greater potency than procaine). To have the same efficacy, low lipid soluble anesthetics (lower potency) must be given in higher concentrations and higher doses than local anesthetics with higher lipid solubility and thus, higher potency.
- Local anesthetics are weak bases. The onset is a function of the pKa, the pH at which there are equal percentages of the ionized and non-ionized forms (eg, 50% ionized, 50% non-ionized). The non-ionized form is able to easily transverse the neural membrane. Local anesthetics with a pKa close to the physiologic pH result in greater concentrations of the non-ionized form leading to a more rapid onset. pKa near physiologic pH: non-ionized base (faster) onset. However, once inside the nerve cell, the non-ionized base attains equilibrium with the ionized from. The ionized form (cation) binds to the receptor within the sodium channel and inactivates it (see Fig. 162.4).

### Box 162.1

**Techniques to Decrease the Pain of Local Anesthetics**

- **Use a topical agent prior to the injection**
- **Use smallest gauge needle possible** (generally, a 27- to 30-gauge needle)
- **Use warmed solution**: Warmed to 98.6°F to 102°F (37°C to 39°C)
- **Inject slowly**
- **Inject into the subcutaneous space, not the dermis**
- **Minimize the number of punctures**
- **Inject from within open wounds, do not inject through the adjacent intact skin**
- **Buffer the local anesthetic**: Mix 1% lidocaine with 8.4% sodium bicarbonate solution in a ratio of 9 parts lidocaine to 1 part sodium bicarbonate (Mixing bupivacaine with bicarbonate can cause precipitation of the anesthetic and is not recommended.)
preferable to diphenhydramine (4 mL normal saline:1 mL 5% diphenhydramine to make a 1% solution) as an alternative local anesthetic in patients with a true lidocaine allergy for several reasons. A randomized controlled trial of lidocaine, benzoyl alcohol, and diphenhydramine for local anesthesia found that the duration of analgesia was longest for lidocaine, and the highest median pain of infiltration occurred with diphenhydramine. Although diphenhydramine has been used as an effective local anesthetic; it can be absorbed systemically and cause sedation. More importantly, it is a tissue irritant, and hyperemia and tenderness at the injection site for several days is common; unpredictable local skin necrosis and sloughing has been reported. If diphenhydramine is used as a local anesthetic, it should be used in a 1% solution because lower concentrations (eg, <1%) may be less effective, and higher concentrations (eg, >1%) probably increase the risk of skin necrosis.

Serious toxicity from local anesthetics is due to their effects on the CNS and to the cardiovascular system (CVS). Early signs of toxicity include numbness or tingling of the lips, metallic taste, muffled hearing, and tinnitus. These symptoms often portend the onset of drowsiness, seizures, status epilepticus, and coma. Direct myocardial depression and pump failure can occur, especially if the patient is on beta blockers or calcium channel blockers; heart block and asystole can also occur. If cardiac arrest is known or presumed to be from local anesthetic toxicity, length of resuscitation should take into consideration time for the negative cardiac effects to wear off. Any of the local anesthetics can have these adverse effects, especially when exceeding recommended doses.

Compared to the amides, the esters have a higher incidence of allergic reactions. Procaine and benzocaine are metabolized to para-aminobenzoic acid (PABA), which has been associated with rare anaphylactic reactions. The metabolites of prilocaine and benzocaine have been associated with methemoglobinemia. Bupivacaine has a higher cardiac toxicity profile than other local anesthetics, but bupivacaine is still widely used and generally safe and effective when used as recommended. In general, the choice of local anesthetic depends more on duration and personal preference than a marked advantage of one specific drug or anesthetic class.

Nerve Blocks

A nerve block is regional anesthesia attained by the injection of a local anesthetic agent near a nerve, nerves, or nerve plexus supplying a particular area. There may be a fairly well circumscribed region of anesthesia (eg, a wrist or ankle block) or an entire limb, termed major regional anesthesia. Nerve blocks are often used to provide anesthesia prior to procedures (eg, reduction of fractures or dislocations and suturing large lacerations). This approach has the advantage of limiting the amount of lidocaine or other anesthetic needed, decreasing the possibility of reaching toxic levels of the local anesthetic. The use of ultrasound-guided nerve blocks in the ED has been increasing due to the increased safety and efficacy found with sonographic visualization of structures. Although there has been much literature on the use of nerve blocks for adults in the ED, there are relatively few studies dealing with the use of nerve blocks for pediatric patients in the ED.

Complications that can occur with any nerve block include needle breakage (more likely if very small and long needles or if needles are bent to perform the block; eg, posterior superior alveolar block), needle damage to anatomic structures (eg, nerves, vessels, visera, pleura, other structures), neurotoxicity, vascular complications (eg, hematoma formation, intra-arterial injection), infection, and bleeding. With any nerve block, providers should review the appropriate anatomy (particularly if performed infrequently), be careful not to exceed maximum doses of anesthetics, and calculate the maximum dose based on actual not ideal body weight. Mixing lidocaine and bupivacaine will give both a rapid onset and longer duration nerve block.

Nonopioid Systemic Analgesics

Nonopioid systemic analgesics (Table 162.5) include acetaminophen (paracetamol), which has analgesic and antipyretic effects but does not have any anti-inflammatory effects. There is no need for any dosage change for mild renal or hepatic impairment. If therapeutic doses are used and there is no alcohol abuse or pre-existing liver disease, then hepatic toxicity is rare. Acetaminophen is an excellent choice for the treatment of mild pain, in combination with opioids for moderate to severe pain, and has several methods of administration, including the IV route. Indications for the IV use of acetaminophen include patients with pain or fever who are unable to take oral medications and those who have impaired gastrointestinal (GI) absorption.

The NSAIDs have analgesic and anti-inflammatory properties. NSAIDs inhibit cyclooxygenase (COX)-1 and COX-2, which decreases the synthesis of prostaglandins, thereby elevating the threshold for nociceptor activation. Nonselective NSAIDs inhibit both COX-1 and COX-2. Side effects of COX-1 inhibition include GI bleeding, renal failure, and platelet dysfunction. In pediatric patients, ibuprofen is the NSAID of choice, because it has fewer side effects than other NSAIDs. NSAIDs may be more effective than acetaminophen at reducing pain from inflammation associated with tissue injury.

Aspirin has analgesic, antipyretic, and anti-inflammatory effects. However, aspirin is not recommended in children and infants due to risk of Reye syndrome, a rapid-onset encephalopathy associated with hepatic dysfunction; for this reason, aspirin should not be used in any individual with chicken pox or flu symptoms.

Opioid Analgesics

Opioids, previously termed narcotics, produce analgesia by binding to opioid receptors in the brain, brainstem, spinal cord, and peripheral nervous system. The main adverse effect of opioids is a dose-dependent respiratory depression with blunting of the responses to hypoxia and hypercarbia; this effect is potentiated when co-administered with other sedative medications. Other side effects are primarily GI (eg, constipation, nausea, vomiting), urinary retention, and pruritus.

There are many routes of administration of opioids. IM is not recommended secondary to injection pain and variable IM absorption. Codeine is a weak opioid that has an increased incidence of side effects compared to other opioids. Up to one-third of patients are considered codeine “non-responders,” due to a genetic trait that interferes with codeine metabolism. As a result, they are unable to create the active metabolites responsible for codeine’s analgesic effects. Meperidine is not recommended due its possible CNS toxicity (eg, seizures, hallucinations, and psychosis) at therapeutic doses and its risk of serotonin syndrome.

Opioid Prescribing and Use. Partially due to an increased focus on treating pain, there has been a tremendous increase in the prescribing of opioids by health care providers in recent years for both adults and pediatric patients. There has also been a concomitant increase in the untoward complications of opioid prescribing, including opioid abuse, addiction, overdose, and deaths.

Americans, with only 4.6% of the world’s population, consume 80% of the global opioid supply, 99% of the global hydrocodone supply, and two-thirds of the illegal drugs. According to the National Hospital Ambulatory Medical Care Survey, the overall use of opioid analgesics in pain-related pediatric ED visits

</table>

**OPIOIDS: ORAL**

Mechanism of action:
- Hydromorphone: Less respiratory depression than other opioids
- Morphone: Central inhibition of norepinephrine and serotonin reuptake, weak affinity for mu receptors
- Oxycodone and acetaminophen: No histamine release and fewer side effects than morphine
- Tramadol: Related to codeine; preferred over codeine
significantly increased from 11.2% in 2001 to 14.5% in 2010. The use of Drug Enforcement Agency (DEA) schedule II agents doubled from 3.6% in 2001 to 7.0% in 2010, whereas there was no significant increase in the use of schedule III, IV, or V agents. In comparison, there was no significant increase in the use of nonopioid analgesics in pediatric ED patients. Increased opioid use was most striking in ED visits that involved adolescents.16 A recent survey indicated that 10.4% of ED patients ages 14 to 20 years old reported nonmedical prescription opioid or sedative use.17 Another report noted that 80% of America's high school students (11 million teens) and 44% of middle school students personally witnessed illegal drug use, illegal drug dealing, illegal drug possession, and other activities related to drug abuse on school grounds.15

Although there is no evidence based literature documenting a clear superiority of opioid versus nonopioid analgesics, there are multiple adverse effects and consequences for both the individual and the community associated with opioid use, misuse, and abuse. Thus, we recommend that opioids be reserved for more severe pain or pain refractory to other analgesics rather than be routinely prescribed. If opioids are indicated, they should be given at the lowest effective dose for a limited duration (eg, 1 week), and the

---

*Typical common doses and maximums are listed. This may not apply to all individuals. Patients differ greatly in their responses to medications, especially opioids. Response may vary due to many factors including age (very young and elderly), previous or chronic exposure to opioids (opioid naive or opioid tolerant), and initial pain severity so opioids should be titrated to effect.

†Use of commercially available brand names does not imply endorsement of any medication or product. They are used because health care providers may be more familiar with brand names than the specific drug name or category or drugs.

‡There are many routes of administration of opioids, but IM is not recommended, because the injection is painful and has variable absorption and, thus, variable efficacy and unpredictable side effects.

§Codeine and meperidine are not included in this table, because they are not preferred and other options are available with fewer side effects.

‖Oral transmucosal fentanyl is not included in the table, because the fentanyl lollipop was associated with a high incidence of side effects, including nausea, vomiting, and respiratory depression; so it was removed from the market.

¶Rectal suppositories available for hydromorphone but are not recommended due to variable absorption.

Another analgesic, such as remifentanil, have been administered for analgesia as part of procedural sedation and analgesia (PSA) but has not yet gained widespread popularity so is not included in the table.

Transdermal patches are available for various medications including lidocaine (Lidoderm) and opioids, fentanyl (Duragesic) and buprenorphine (Butrans), but these are generally for chronic pain. They may be encountered in patients with chronic pain, such as cancer patients, but are not generally used for the treatment of acute pain in the ED.

If the hydrocodone or oxycodone or morphine are in the extended release or sustained form, which is for chronic pain, the tablets should be swallowed whole and should not be moistened, dissolved, cut, crushed, broken, or chewed, because this changes the formulation from sustained release to immediate-acting, which can lead to an acute overdose.

Note: Both hydrocodone (Hydingla ER, Zohydro) and oxycodone (Oxecta, OxyContin, Roxicodone) are available in formulations without the acetaminophen component, with the same dosage of hydrocodone or oxycodone, respectively, as for the combinations with acetaminophen. However, they are not frequently prescribed in these formulations without the acetaminophen.

ED, Emergency department; GI, gastrointestinal; IM, intramuscular; IV, intravenous; NPO, nil per os (nothing by mouth); NSAID, nonsteroidal anti-inflammatory drug; ODT, orally disintegrating tablets; PCA, patient-controlled analgesia; PO, per os (by mouth); PR, per rectal.
prescriber should consider the patient’s risk for opioid use, abuse, or diversion.16

Low Dose Ketamine for Treatment of Pain

Low dose ketamine has been successfully used in adults and pediatric patients for the treatment of acute pain.17 Pediatric studies are small case series in hospitalized patients (eg, non-ED setting) for the treatment of acute pain from cancer or sickle cell disease. Doses for the treatment of acute pain are lower than used for sedation and vary. A commonly used dose is 0.15 mg/kg (range 0.1 to 0.2 mg/kg). Higher doses (eg, 0.3 mg/kg) have been associated with a higher incidence of side effects. Continuous infusions have also been used, in the range of 0.1 to 0.2 mg/kg/hour. Adverse events noted with low dose (0.15 mg/kg) ketamine in one adult study include nausea (15%), vomiting (10%), dysphoria (10%), and an abnormal taste sensation (5%). One adult study reported an overall 6% incidence of side effects with low dose ketamine, which included a 3.5% incidence of dysphoria, 1.5% transient hypoxia, and 1% vomiting. Dizziness, fatigue, and headache have also been reported. Similar data is not yet available for pediatric patients.

Reversal Agents

Naloxone is used for the reversal of opioids effects on the mu receptors (eg, sedation and respiratory depression). Although the half-life is about 1 hour, the clinically effective duration of action may be much less (eg, 20 to 60 minutes). Due to longer half-lives of many opioids, re-dosing or an infusion of naloxone is often needed with opioid overdoses. The usual dose for full reversal of opioid intoxication is 0.1 mg/kg/dose with an initial maximum dose of 2 mg for infants and children 5 years old and younger or 20 kg and less; for children >5 years or >20 kg and adolescents, the dose is 2 mg. The dose may be repeated every 2 to 3 minutes if there is no response. The IV route is preferred, but intraosseous (IO) can be used if there is no IV line. It may also be given intramuscularly or subcutaneously, but the onset of action may be delayed, especially if there is poor perfusion. Naloxone may be administered intranasally at a dose of 2 mg (1 mg per nostril) for adolescents (13 years old and older), and is often given by emergency medical service (EMS) in the field or at home for acute opioid overdoses. Naloxone can also be administered endotracheally at 2 to 3 times the initial IV dose. For reversal of respiratory depression with therapeutic opioid doses, lower doses may be used with an initial dose of 0.001 to 0.005 mg/kg/dose with some recommending 0.001 to 0.015 mg/kg/dose intravenously, intramuscularly, or subcutaneously; with the dose titrated to effect or repeated every 2 to 3 minutes as needed until the desired response is obtained.

Flumazenil antagonizes the action of the benzodiazepines at the gamma-aminobutyric acid (GABA) receptor. It has a half-life of about 1 hour, but the clinically effective duration of action may be much less (20 to 60 minutes). Flumazenil can only be given intravenously. Flumazenil may be given when there is an overdose of benzodiazepines administered for clinical reasons and only in a patient who is not benzodiazepine habituated. In individuals who overdose on benzodiazepines, it is likely that they are habituated and on benzodiazepines chronically. In these cases, benzodiazepine withdrawal may be associated with status epilepticus and even death. Thus, except in the acute iatrogenic overdose setting, the use of flumazenil is not recommended. Patients who co-ingest benzodiazepines and tricyclic antidepressants may develop intractable seizures after flumazenil administration. Thus, use of flumazenil should be reserved for patients with an uncomplicated benzodiazepine overdose, no evidence of tricyclic antidepressants use (eg, no electrocardiogram [ECG] findings and no anticholinergic signs and symptoms), no history of seizure disorder, and no history of benzodiazepine habituation. For benzodiazepine reversal with procedural sedation or anesthesia, the initial dose of flumazenil for infants, children, and adolescents is 0.01 mg/kg (maximum 0.2 mg), which may be repeated after 45 seconds and then every minute up to 4 additional doses. The maximum total cumulative dose is 1 mg or 0.05 mg/kg, whichever is lower. In adults, the initial dose is 0.2 mg, which may be repeated for a total of 5 doses with a total cumulative dose of 1 mg. Flumazenil has a black box warning. In general, it is used infrequently and only for benzodiazepine reversal with procedural sedation or anesthesia.

OUTCOMES

There are moral, ethical, legal, and regulatory reasons to adequately treat pain. Oligoanesthesia, the failure to adequately treat pain, continues despite increasing literature demonstrating that pain is too often undertreated. Children and infants, the elderly, individuals with limited cognitive ability, and ethnic and social minorities have a greater risk of oligoanesthesia. The negative consequences of undertreating pain include increasing the patient’s pain threshold and predisposing patients to developing chronic pain syndromes. Inadequate analgesia may lead to harmful physiologic consequences, including an increase in stress hormones and increased sympathetic outflow. This results in an increase in catabolism, myocardial oxygen consumption, production of carbon dioxide, and peripheral vascular resistance, as well as an impaired immune response.

The Joint Commission (TJC) mandates that hospitals adopt a pain management quality improvement program, which includes the measurement, documentation, and therapy for pain. Patient satisfaction and the patient experience are gaining greater importance, especially since the Centers for Medicare and Medicaid Services (CMS) and the National Committee on Quality Assurance require public reporting of patient satisfaction data for participating health plans. In the future, hospital and physician payment will be based on patient outcomes, as well as patient satisfaction. The positive relationship between adequate treatment of pain and patient satisfaction has been documented for all ages of patients, including children and infants. Eliminating or minimizing the pain of medical procedures can also lead to greater procedural success rates.
Patients of all ages experience pain, even infants, neonates, and premature babies.

Oligoanesthesia, the inadequate treatment of pain, has many short-term and long-term consequences: worse patient outcomes, increase in patient’s pain threshold, and development of chronic pain.

Pain management may include a combination of techniques: analgesics, topical anesthetics, local anesthetic injections, and nonpharmacologic interventions.

Nonpharmacologic interventions to decrease pain or anxiety include oral sucrose in infants; parental presence; physical measures, such as heat or cold therapy and splinting for musculoskeletal injuries; and behavioral or cognitive measures, such as distraction and play therapy.

Topical anesthetics are recommended to decrease the pain of minor procedures, such as venipuncture or IV cannulation.

Techniques for decreasing the pain of intradermal injections include topical agent prior to the intradermal injection; slowly injecting warmed, buffered local anesthetic solution from within the wound with the smallest gauge needle possible; and limiting the number of needle punctures.

When using large amounts of local anesthetics in small children or infants, calculate the drug dose to avoid toxicity; a 1% solution = 1 g/100 mL or 10 mg/mL.

Procedural sedation and analgesia (PSA) requires pre-sedation evaluation; sufficient monitoring (during and after the procedure) by qualified individuals capable of dealing with any adverse events that may occur; age-appropriate equipment (including airway equipment) and medications (including reversal agents and advance life support drugs); and discharge criteria for when the patient is fully awake, returns to baseline with stable vital signs, and is able to be discharged in the care of a responsible adult.

Overall, preprocedural fasting is not necessary for most emergency patients, because large studies show no clinically significant differences with airway complications, emesis, or other adverse effects between groups of patients stratified by their preprocedural fasting status.

Choice of sedative and analgesic for PSA depends on many variables including patient factors and the procedure to be done. Slow titration of medications can achieve the desired level of sedation and analgesia while minimizing risk of adverse events.

CHAPTER 162: QUESTIONS & ANSWERS

162.1. When do most adverse events associated with emergency department (ED) procedural sedation occur?
A. During the manipulation or intervention
B. 5 to 20 minutes after the last sedative dose
C. 20 to 30 minutes after the last sedative dose
D. 30 to 60 minutes after the last sedative dose
E. 60 to 90 minutes after the last sedative dose

Answer: B. High-risk times are 5 to 20 minutes after the last medication administration and at the completion of the procedure when there is no longer a painful stimulus but the patient remains sedated.

162.2. Which of the following modalities has proven most effective for monitoring patients undergoing procedural sedation?
A. Capnometry or capnography
B. Cardiac rhythm monitoring
C. Continual direct visual observation of qualitative clinical signs
D. Documented respiratory rate
E. Pulse oximetry

Answer: C. The patient’s ability to follow commands in response to varied levels of stimulation and direct observation of the ventilatory status have been the most reliably documented methods of assessing the level of consciousness during procedural sedation. Pulse oximetry is a reliable adjunct, but it identifies hypoventilation late, especially when used with supplemental oxygen. Cardiac monitoring has been shown to be helpful in older patients or in those with a history of cardiac disease, but there is no evidence that it is of any benefit in young healthy patients. End-tidal carbon dioxide monitoring has been shown to be useful to detect inadequate ventilation earlier than oximetry, especially when direct observation of the patient is difficult, but no studies have demonstrated an effect on clinical outcome to date. Recently, the American Society of Anesthesiologists (ASA) updated its procedural sedation standards to include capnography during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs. Respiratory rate alone is an insensitive indicator of adequacy of ventilation.

162.3. Which of the following agents is matched with the correct associated side effect?
A. Etomidate—limited (30-minute) duration of sedation
B. Ketamine—laryngospasm
C. Methohexital—venoiritation
D. Pentobarbital—seizures
E. Propofol—myoclonus

Answer: B. Ketamine has been associated with laryngospasm in children younger than 3 months old and those with a respiratory infection. The following are the other correct associations:

- Etomidate—myoclonus
- Methohexital—seizures
- Pentobarbital—30-minute duration
- Propofol—venoiritation

162.4. Which of the following statements regarding the use of ketamine is false?
A. Benzodiazepine coadministration has not been shown to reduce the incidence of emergence phenomenon in children.
B. Despite increased secretions, airway reflexes are generally well maintained.
C. Hypotension is common.
D. Profound analgesic and sedative effects occur with minimal respiratory depression.
E. Repeat doses are well tolerated in longer procedures.

Answer: C. Ketamine increases the release of catecholamines upon administration and supports blood pressure well. It also decreases smooth muscle tone in the bronchial tree and may have a benefit in patients with reactive airways disease. Several studies have failed to show benefit with the concurrent administration of low-to-moderate dosages of benzodiazepines in preventing emergence phenomenon in children. These studies have shown a slightly increased risk of side effects. Their routine use is discouraged and should be reserved for the actual treatment of severe emergency phenomenon.

REFERENCES

162.5. Which of the following statements regarding the use of propofol is true?
A. Propofol has a long duration of action and provides significant analgesia.
B. Propofol has significant antiemetic properties.
C. Propofol is cerebroprotective.
D. Propofol is well tolerated in volume-depleted patients.
E. The use of “ketofol” (ketamine in combination with propofol) is clinically superior to the use of propofol alone.

Answer: B. Propofol is an ultra–short-acting, sedative-hypnotic, cerebroprotective agent with no analgesic but profound antiemetic properties. Its adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Preload-dependent patients are particularly susceptible to hypotension. Its combined use with ketamine is common. The two agents are felt to have synergistic effects that balance each other’s deficits. The combined use has been shown to improve provider satisfaction, sedation quality, and decrease emesis but has not been shown to be clinically superior to either agent used alone regarding respiratory depression, airway complications, or improved recovery times.

162.6. Which of the following statements is true regarding the need for fasting before procedural sedation?
A. A 6-hour period of fasting is required after the ingestion of liquids or solids before procedural sedation.
B. Preprocedural fasting is required in all circumstances.
C. The recommendation for preprocedural fasting is based on controlled trials involving patients undergoing procedural sedation.
D. The risk of vomiting and the loss of the airway protective reflexes is an extremely rare occurrence during procedural sedation.
E. There is an increased risk of aspiration during procedural sedation after a liquid or solid meal.

Answer: D. The American Society of Anesthesiologists (ASA) currently recommends a period of 2 hours after ingestion of clear liquids, a period of 4 hours after ingestion of breast milk, and a period of 6 hours after ingestion of other liquids or solids before the performance of procedural sedation. This recommendation is based on expert consensus and extrapolated from data on patients receiving general anesthesia and manipulation of the airway during intubation and extubation. There are no published studies showing increased risk of aspiration after a liquid or solid meal, nor benefits of fasting before procedural sedation. There are large studies showing no clinically significant differences with airway complications, emesis, or other adverse effects between groups of patients stratified by their preprocedural fasting status. Adherence to the ASA preoperative fasting guidelines for procedures is not necessary in emergency department (ED) patients undergoing procedural sedation and analgesia (PSA).
Pediatric Resuscitation

CARDIAC ARREST

Principles

Pediatric cardiac arrest is rare, but the consequences are dire when considering lost years of life and productivity. The incidence and survival for pediatric cardiac arrest varies with the location of the arrest, patient’s age, and the mechanism. Most cardiac arrests encountered in the emergency department (ED) occur outside the hospital, from medical causes in infants and traumatic causes in older children.1 Most infant arrests occur before 3 months of age, reportedly as a result of sudden infant death syndrome (SIDS).2 The incidence of cardiac arrest in infants approaches the incidence of arrest in adults. The incidence of nontraumatic cardiac arrest in older children is 30 to 50 times less common than infants and adults.

Previous literature suggests survival following cardiac arrest in children is poor; however, this is largely based on studies that fail to differentiate survival among infants and older children. Infants survive infrequently (2% to 3%) but older children survive (9%) more commonly than adults (5%).3 In addition, survival for all children following cardiac arrest has improved substantially over the last 30 years.4 The frequency of survival with good neurologic outcome has been estimated at 1% to 12%.4 These estimates arise largely from studies focusing on neurologic status at 1 month, yet children often continue to demonstrate improvements in their neurologic statuses for years.4 Most traumatic arrests in children are often fatal; resuscitative thoracotomy in selected patients may improve survival.1,5-9

Pediatric resuscitations are relatively rare, limiting provider proficiency. In a recent retrospective review, less than half of emergency clinicians had completed any critical care procedures (eg, cardioversion, intubation, intraosseous line placement) on children in the ED in the preceding year.6 Moreover, 75% of the procedures completed were intubations. Procedures that no providers in the study had performed included cardiac pacing, needle cricothyroidotomy, diagnostic peritoneal lavage, thoracentesis, arterial line placement, or venous cutdown line placement. This study was conducted at a busy children’s hospital; the frequency of critical pediatric procedures is likely lower in general EDs. 

Lack of experience limits provider proficiency. In the absence of actual clinical experience, providers often rely on didactic resuscitation courses. However, knowledge retention after these courses is poor.11,12 As a result, many providers remain uncomfortable managing critically ill children.13 This discomfort can lead to insufficient interventions for fear of harming a child, or alternatively, excessive interventions unlikely to be of benefit.

Pathophysiology

Most nontraumatic cardiac arrests in children arise from respiratory etiologies, particularly drowning, asphyxia, and respiratory failure.14 The typical progression is from respiratory failure to shock, and finally to bradycardia and loss of circulation. Pediatric advanced life support (PALS) guidelines have largely focused on the treatment of these respiratory emergencies. However, recent international population based studies suggest cardiac causes account for approximately a third of pediatric medical arrests.13,14

Another 21% of pediatric arrests follow trauma. These frequencies are in stark contrast to adults, where two-thirds of arrests are attributed to cardiac etiologies and 5% to 10% are traumatic.17,18 The differences in the etiology of arrests between adults and children have significant implications for management; arrests from respiratory causes require an emphasis on ventilatory support, oxygen delivery, and maintenance of perfusion, whereas arrests from cardiac causes require a more directed emphasis on restoring perfusion and treatment of underlying dysrhythmias.

The most common presenting pediatric arrest rhythm is asystole, occurring in two-thirds of children. Pulseless electrical activity and bradycardia are the next most common presenting rhythms. Unlike adults, ventricular fibrillation and tachycardia are rare, occurring in less than 10% of children.15 These dysrhythmias become more common in adolescents, in children with congenital heart disease, and they also often arise during the course of prolonged resuscitations.

Clinical Features

The absence of a pulse, respiratory effort, and responsiveness constitute cardiac arrest. While identifying respiratory effort and responsiveness are relatively straightforward, detecting a pulse in a pediatric patient can prove difficult. Health care providers have been found to identify a pulse when not present in 26% of children undergoing extracorporeal membrane oxygenation (ECMO). Moreover, providers have been found to take an average of 9 (±6) seconds to detect a brachial pulse and 29 (±14) seconds to determine a pulse was not present in children.20 Current guidelines suggest lay people should initiate cardiopulmonary resuscitation (CPR) in children without performing a pulse check; any child that is unresponsive and apneic should receive CPR. For emergency clinicians, a 10-second pulse check is appropriate. If no pulse is detected in 10 seconds, CPR should be initiated without delay. The adverse effects of delayed CPR outweigh the effects of CPR for an apneic, unresponsive child with a pulse.

Location to Perform Pulse Check

The ideal location for palpation of a child’s pulse is unclear. There are few studies comparing sites, and they are conducted in the operating room with conflicting results. In infants, the carotid pulse can be difficult to detect compared to the brachial or femoral pulse. In adolescents, the carotid is the easiest location to identify a pulse. In children in cardiac arrest, auscultation of the heart or palpation of the apical impulse can be misleading; patients with pulseless electrical activity can have an apical impulse or auscultated heartbeat without central pulses or adequate perfusion. If ever in doubt about the presence of a pulse, providers should err on the side of initiating compressions.
Recognizing Imminent Arrest

Anticipating impending cardiac arrest allows for early interventions that may prevent progression. Abnormal vital signs, based on age-specific norms, are often the best indicator of imminent arrest in an ill child. These values can be difficult to remember, but providers can recognize several key features (Box 163.1).

Management

The paucity of pediatric out-of-hospital cardiac arrest results limits available evidence on its management. Most pediatric guidelines are consensus-based and much is extrapolated from adult data.21-24 The American Heart Association (AHA) guidelines for management are illustrated in Figure 163.1. These pediatric guidelines are generally intended for use on children until puberty (ie, axillary hair in males and breasts in females).

Compressions-Airway-Breathing

During the initial no-flow state of cardiac arrest, the priority is initiation of flow. This priority has led to a change in the sequence of “airway-breathing-compressions (A-B-C)” to “compressions-airway-breathing (C-A-B).” CPR begins with compressions, rather than “look, listen, and feel” for respirations, to avoid delays in the initiation of blood flow. In addition, this approach may render bystanders to an arrest more likely to provide CPR, because compressions are prioritized over ventilations, which bystanders are more reluctant to provide. This is particularly helpful in children; bystander CPR improves pediatric survival but is infrequently administered.

There is debate about the true benefits of the C-A-B approach in children, where arrests are more commonly from a respiratory etiology, potentially requiring respiratory support to correct. However, no delays were found in the initiation of ventilations with the C-A-B approach compared to the A-B-C approach in simulated respiratory arrest in children.25 Moreover, the C-A-B approach led to prompter recognition of cardiac arrest. Because multiple providers are available in the ED, initiation of compressions can and should begin concurrently with ventilations.

**Compressions.** High quality compressions improve outcomes but are rarely performed. When administered appropriately, compressions generate one-third of a child’s normal cardiac output and a coronary artery perfusion pressure of 10 mm Hg. Compressions can improve blood pressure, return of spontaneous circulation, and survival.26-27 Despite these findings, numerous studies have shown that inadequate compressions are the norm.27 A prospective, observational study of in-hospital pediatric arrest found AHA guidelines for chest compressions were achieved in 54% and depth in 19% of children.27 In an academic pediatric ED study, compression rates more than 100 per minute were observed in 87%, but recommended compression to ventilation ratios were achieved in only 40%, with frequent pauses in compressions.24

Compression technique influences cardiac output, and those over the lower part of the sternum improve cardiac output. This is particularly important in infants, whose hearts reside inferior to the lower third of their sternums. In these younger children, encircling the chest with both hands and compressing with the thumbs while squeezing the thorax with the remaining fingers yields greater cardiac output than compression with two fingers (Table 163.1). The AHA suggests utilizing the heel of one hand to administer compressions to children 1 to 8 years old, but a study of simulated compressions suggested a two-handed technique, identical to that performed on adults, is easier and generates higher pressures. When feasible, a resuscitation board should be placed under children receiving chest compressions; at a minimum, the child should be supine on a firm surface.

The ideal compression depth and rate is unknown, but the AHA recommends pushing “hard and fast.” Compressions should be deep enough to achieve optimal cardiac output without being

Pediatric Cardiac Arrest Algorithm – 2015 Update

1. Start CPR
   - Give oxygen
   - Attach monitor/defibrillator

2. Yes
   - VF/pVT

3. Shock

4. CPR 2 min
   - IO/IV access

5. Yes
   - Shock

6. CPR 2 min
   - Epinephrine every 3-5 min
   - Consider advanced airway

7. Yes
   - Shock

8. CPR 2 min
   - Amiodarone or lidocaine
   - Treat reversible causes

9. No
   - Asystole/PEA

10. CPR 2 min
    - IO/IV access
    - Epinephrine every 3-5 min
    - Consider advanced airway

11. CPR 2 min
    - Treat reversible causes

12. No
    - Asystole/PEA → 10 or 11
    - Organized rhythm → check pulse
    - Pulse present (ROSC) → post-cardiac arrest care

   Go to 5 or 7

CPR quality
- Push hard (≥1/3 of anteroposterior diameter of chest) and fast (100-120/min) and allow complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 15:2 compression-ventilation ratio.

Shock energy for defibrillation
- First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥4 J/kg, maximum 10 J/kg or adult dose.

Drug therapy
- Epinephrine IO/IV dose: 0.01 mg/kg (0.1 mL/kg of 1:10 000 concentration). Repeat every 3-5 minutes.
  If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration).
- Amiodarone IO/IV dose:
  Initial: 5 mg/kg bolus during cardiac arrest. May repeat up to two times for refractory VF/pVT.
  Maintenance: 20-50 mcg/kg per minute infusion (repeat bolus dose if infusion initiated >15 minutes after initial bolus therapy).
- Lidocaine IO/IV dose:
  Initial: 1 mg/kg loading dose. Maintenance: 20-40 mcg/kg per minute infusion (repeat bolus dose if infusion initiated >15 minutes after initial bolus therapy).

Advanced airway
- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

Return of spontaneous circulation
- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible causes
- Hypovolemia
- Hypoxia
- Hypo/hyperkalemia
- Hypothermia
- Hypoglycemia
- Tension pneumothorax
- Coronary artery disease
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

Fig. 163.1. The American Heart Association (AHA) guidelines algorithm for management of infants and children in cardiopulmonary arrest. CPR, Cardiopulmonary resuscitation; ET tube, endotracheal tube; IO/IV, intraosseous/intravenous; PEA, pulseless electrical activity; ROSC, return of spontaneous circulation; VF/pVT, ventricular fibrillation/pulseless ventricular tachycardia.
so deep as to cause injuries to other vital organs. Attempts to increase depth excessively can result in leaning, which reduces coronary artery perfusion pressure and cardiac output.29 Guidelines suggest compressing the chest half of the anteroposterior diameter of the child, but this estimate leads to relatively deeper compressions than recommended in adults, where guidelines provide an absolute depth for compression. Moreover, it can be extremely difficult to assess the proportion of anteroposterior compression depth during CPR. As a result, it is more practical to focus on absolute depths; we recommend 1½ inches in infants and 2 inches in older children.

Similarly, the exact rate of compressions to generate ideal cardiac output is unclear. Rates more than 100 compressions per minute improve cardiac output, coronary artery perfusion pressure, and survival compared with rates less than 90 compressions per minute in children.26 However, attempts to exceed 120 compressions per minute likely diminish the quality of compressions. In adults, there is an association between survival and compression rates of 100 to 119 compared to faster or slower rates.30 High quality compressions diminish after 2 minutes. At this point, providers may deny fatigue and be able to maintain the rate of compressions, but depth of compressions decreases substantially. This reduction in quality worsens with time.31 Pauses in compressions to provide defibrillation or switch compressors create substantial drops in coronary artery perfusion pressure; in adults, pauses more than 20 seconds increase the odds of mortality by 50%.32 Provider switches account for 57% of no-compression/no-flow time observed in CPR.

Finally, the appropriate ratio of compression to ventilations is unknown. Animal models indicate the amount of ventilation required during CPR is much lower than with a normal perfusing rhythm, likely due to the lower cardiac output in CPR. The AHA recommends 30:2 compressions to ventilations for single rescuers and 15:2 for two rescuers. However, the 15:2 ratio may yield insufficient compressions per minute in older children, and a 30:2 ratio may be considered. Over half of CPR observed in a study of pediatric arrest involved ventilations in excess of recommendations, with 20% over twice the recommended ventilation rate.33 Once an advanced airway is in place, compressions should not be interrupted for ventilations delivered at 8 to 10 breaths per minute.

Notably, although resuscitation guidelines provide exact rates, depths, and ratios of compressions to ventilations, these recommendations are largely based on consensus. There are no randomized control studies comparing the impact of exact ratios, frequencies, and depths of compressions on survival. Rather than focusing on strict adherence to exact guidelines, emergency providers should focus on ensuring compressions are appropriately located and administered rapidly without interruptions.

Feedback improves the quality of compressions. Quantitative feedback is most helpful, because qualitative assessments by providers can be difficult. Accelerometers and force sensors provide real-time data on compression rate and force. These feedback devices improve adherence with compression guidelines amongst children in cardiac arrest.37 Despite proven benefits, less than 5% of hospitals employ feedback devices regularly during resuscitation.38 End-tidal carbon dioxide (ETCO2) also serves as an adjunct measure of the adequacy of compressions.35,36 In the low-flow state of CPR, the flow of venous blood to the lungs serves as the rate-limiting step for the elimination of CO2 as opposed to ventilation. As a result, exhaled CO2 increases with cardiac output. In animal models, using target ETCO2 levels to guide compressions performs as well as using video and verbal feedback.39

Ventilation. Although life-threatening airway emergencies in children are rare, most critical illness in children stems from respiratory etiologies; therefore, emergency clinicians should be well versed in the management of the pediatric airway.40 In a survey of pediatric ED directors, nearly two-thirds reported their ED had inadequate airway management opportunities to maintain provider proficiency; thus continuing education including skill practice is recommended to maintain skills. For an in-depth discussion of the management of the pediatric airway, see Chapter 161.

Bag-mask ventilation may be preferred over endotracheal intubation for inexperienced providers managing children in cardiac arrest. A randomized trial of intubation versus mask ventilation for out-of-hospital pediatric arrest supports this approach.35 There was no difference in survival to hospital discharge or good neurologic outcome between tracheal intubation by emergency medical service (EMS) and bag-mask ventilation alone. Similarly, a recent population-based observational study in adults found survival was lower for out-of-hospital intubation (odds ratio [OR] 0.45; 95% confidence interval [CI], 0.37 to 0.55) compared to bag-mask ventilation.36 Similar to out-of-hospital intubations, ED-based pediatric intubations that require multiple attempts are associated with adverse outcome. Under these circumstances, a focus on delivery of high quality bag-mask ventilation as opposed to endotracheal intubation should be considered.

Compression-Only Cardiopulmonary Resuscitation

For arrests secondary to ventricular fibrillation, patients often have a reservoir of oxygen in their lungs and can maintain adequate arterial partial pressure of oxygen (PaO2) for 5 minutes with compressions alone. In contrast, animal studies of arrests from respiratory causes show that compression-only CPR leads to rapid depletion of oxygen reservoirs and increased CO2 and lactate. In a non-randomized observational study of 5,170 children with out-of-hospital cardiac arrest, children with a non-cardiac etiology for their arrest receiving conventional CPR had a more favorable neurological outcome than compression-only CPR (OR 5.5; 95% CI, 2.5 to 17). In children with a cardiac etiology for their arrest, conventional CPR and compression-only CPR performed similarly (OR for good neurologic outcome: 1.2; 95% CI, 0.6 to 2.7).

Compression-only CPR is better than no CPR. Bystander CPR improves outcomes but less than half of children receive it.3 Allowing bystanders to be more willing to perform compression-only CPR, and this should be encouraged compared to no CPR. In the ED, pediatric CPR should include compressions and ventilations.

Defibrillation. Although ventricular fibrillation and pulseless ventricular tachycardia are rarely the presenting rhythm in children, they arise at some point during 25% of pediatric resuscitations.40 Children with these rhythms are more likely to survive than children or adults with other rhythms. The shorter the duration between onset of the rhythm and defibrillation, the greater the likelihood of achieving return of spontaneous circulation. No other procedures, including establishment of an airway, should delay defibrillation. While awaiting defibrillation, providers should focus on administering high quality compressions without interruptions until the defibrillator is in place and charged.

Defibrillation applies asynchronous current to the heart. Both paddles and pads provide adequate energy, assuming gel is placed on the paddles and pads are firmly attached to the chest wall. The largest pads available that fit on the child’s chest without touching will decrease transthoracic impedance and provide greater energy to the heart. Anteroposterior and anterolateral positioning of pads provide equivalent energy to the heart.41 When available, providers should use pediatric paddles for children younger than 8 years old. If not available, adult-sized pads can be employed with anteroposterior placement, minimizing contact between the pads. Currently, there is insufficient evidence to support the safety of
Medications for Cardiac Arrest. There are no high quality randomized control studies showing improvement in survival to hospital discharge or neurologic outcome with any medications administered during pediatric cardiac arrest.45 Moreover, there is mounting evidence to suggest that certain commonly administered medications are associated with decreased survival and poorer neurologic outcome. Bicarbonate continues to be used routinely (68% of pediatric in-hospital cardiac arrests) despite poorer neurologic outcome. The primary disadvantage of higher energy doses is damage to the myocardium, but animal studies suggest long-term myocardial necrosis only occurs with doses more than 10 J/kg. The only circumstance where providers would potentially encounter such high doses is when utilizing adult paddles on infants. However, when presented with an infant in ventricular fibrillation and no other options, utilization of the adult paddles is appropriate. We recommend starting defibrillation at 2 J/kg, increasing to 4 J/kg with the second defibrillation, and increasing to 10 J/kg for third and subsequent shocks. After a failed defibrillation attempt, compressions should immediately resume without stacked defibrillation attempts.

Vascular Access. The particular site of vascular access is less important than its timely acquisition. Obtaining central venous access is not crucial early in resuscitation, because peripheral venous and intraosseous drug administration produce similar onset of drug action and peak levels for the commonly administered resuscitation drugs.28,50 Peripheral venous access, including the external jugular vein, is typically the easiest method. However, in children in arrest or imminent arrest, concurrent attempts at intraosseous access often save time.

Intraosseous access is typically more successful and faster with minimal complications compared to peripheral or central access in critically ill patients.50-52 Long-term follow up has shown adverse impact on bone growth from intraosseous placement is rare. Directing the needle away from the growth plate during insertion reduces the risk of injury to the growth plate. Frequent checks around the insertion site are necessary, because excessive insertion of fluids into needles misplaced in the subcutaneous tissue can lead to compartment syndrome. Powered intraosseous insertion devices, such as the EZ-IO (Vidacare), decrease insertion times (77% in <10 seconds) and improve the frequency of successful insertion (>90%); although, other powered devices that require calibration, such as the Bone Injection Gun (WaisMed) may delay insertion and reduce the frequency of success.53,64

In young children, the tibia and femur are preferred, because their marrow cavity is well developed. When administering fluid through an intraosseous line, manual pressure is helpful to overcome the resistance of the marrow cavity. Multiple injections of smaller (10 cc) syringes of normal saline (ie, “saline flushes”) may be used to resuscitate infants and small children through an intraosseous needle. Surveys also suggest providers often unnecessarily delay attempts at intraosseous access while attempting peripheral or central access.55,67 Central line access should be established for prolonged resuscitations requiring vasopressors or large volumes of fluid. The femoral vein is the easiest site of cannulation in young children and avoids interference with CPR.

Post-Arrest Care. Following initial resuscitation of a child in cardiac arrest, focus should shift to treating the underlying etiology of the arrest, minimizing brain injury, and improving end-organ perfusion. Post cardiac arrest patients develop a sepsis-like syndrome with elevations in inflammatory markers, myocardial dysfunction, systemic ischemia, and multiple organ dysfunction. Table 163.3 outlines several approaches to mitigate these effects.
We endorse the recommendation from the American College of Emergency Physicians (ACEP) and American Academy of Pediatrics (AAP) that family be given the option of being present during their child’s resuscitation. The limited evidence to support this recommendation is primarily descriptive or survey-based. Most families want to be present for the resuscitation of their child. Centers performing high volumes of ECMO or with rapid response teams to initiate timely cannulation have better outcomes.70,71

### Disposition

**Family Presence.** We endorse the recommendation from the American College of Emergency Physicians (ACEP) and American Academy of Pediatrics (AAP) that family be given the option of being present during their child’s resuscitation. The limited evidence to support this recommendation is primarily descriptive or survey-based. Most families want to be present for the resuscitation of their child, and when asked after being present, they report that they would repeat the experience, even in situations where their child died. Families report their presence comforts their children, helps them appreciate the efforts of providers, facilitates their understanding of the gravity of the situation, and promotes after witnessed arrest with ventricular fibrillation. Moreover, avoidance of hyperthermia with cooling blankets and antipyretic medications is beneficial.

When readily available, providers should also consider ECMO early in an arrest course. Although initial studies suggested ECMO provided greater benefits primarily for patients with underlying cardiac disease, a recent retrospective analysis also identified benefits for children with non-cardiac etiologies for their arrest. Centers performing high volumes of ECMO or with rapid response teams to initiate timely cannulation have better outcomes.70,71

Hypotension after return of circulation is a predictor of mortality. Although vasopressors can help maintain end-organ perfusion in the setting of post-arrest myocardial dysfunction, its use has not been associated with improved survival. There are no randomized studies of comparing the performance of particular vasopressors for pediatric cardiac arrest. In the absence of strong evidence, we administer norepinephrine, which has been shown to cause fewer arrhythmias than dopamine in adults. Concurrent evidence, we administer norepinephrine, which has been shown to cause fewer arrhythmias than dopamine in adults. Concurrent evidence, we administer norepinephrine, which has been shown to cause fewer arrhythmias than dopamine in adults.
the grieving process. In contrast, surveyed providers frequently are reluctant to have families present, often due to a mistaken assumption that parents will be critical of their work.72 In the only randomized study of family presence during trauma resuscitations in the pediatric ED, 93% of physicians reported increased stress from family presence. However, the adverse effects of family presence seemed limited to stress on the emergency clinician, because no differences were detected in clinical care variables. Other studies have confirmed family presence rarely hinders care. However, the adverse effects of family presence seemed limited to stress on the emergency clinician, because no differences were detected in clinical care variables. Other studies have confirmed family presence rarely hinders care. Concerns about family presence prolonging resuscitation efforts also seem unfounded. In most situations, the benefits to the family are helpful. Families should be counseled on anticipated events prior to entering the resuscitation. They should be informed that their presence in the resuscitation is their decision; although, they can be asked to leave if they impede medical care. Designated nurses or social workers with training in grief counseling and free of clinical responsibilities can focus on the family, explaining steps in the resuscitation and answering questions.

**Termination of Resuscitation.** There are no universal criteria to guide the termination of a pediatric resuscitation. Providers are less comfortable terminating efforts in children than adults, often resulting in prolonged, futile resuscitations that increase stress on families and staff. There are numerous anecdotal reports of children surviving with good neurologic outcome after prolonged resuscitations, but these often involve in-hospital arrests or arrests with prompt access to ECMO.73 Several variables, including length of resuscitation, unwitnessed arrest, initial cardiac rhythm, administration of multiple doses of epinephrine, administration of atropine, and ETCO2 ≤10 mm Hg have been associated with poor survival and neurologic outcome.14,23-25 However, none of these variables possess sufficient discriminative ability to provide absolute cutoffs for termination of resuscitation. Perhaps the most predictive variable is duration of resuscitation; additional minute of pediatric CPR, the frequency of survival decreases by 2.1% and favorable neurological outcome by 1.2%.74 For traumatic arrest, guidelines suggest prehospital termination after 30 minutes of unsuccessful resuscitation.76 Such guidelines

and prospective ED implementation of sepsis treatment decreases mortality in children with severe sepsis and septic shock, that adherence to the overall bundle of ACCM recommendations mortality.84-86 Variation and uncertainty exist in specific elements and ascertainment methods accounting for this wide range.78-80

Pediatric sepsis prevalence measured by the point prevalence study showed that 8% of children in the intensive care unit (ICU) have severe sepsis.78,79 Mortality estimates for severe sepsis in pediatrics are 9% to 25%, with variation in location and ascertainment methods accounting for this wide range.78-80 Pediatric sepsis prevalence measured by the International Classification of Diseases, 9th edition, Clinical Modification code has increased in the last decade, whereas mortality has decreased.78,80

Decreasing mortality may be attributable to consensus recommendations from the American College of Critical Care Medicine (ACCM) and international experts.81,82 Although increasingly supported by growing research in pediatric sepsis, the majority of recommendations for sepsis care in children are based on low-grade evidence.83 Nonetheless, studies have demonstrated that adherence to the overall bundle of ACCM recommendations decreases mortality in children with severe sepsis and septic shock, and prospective ED implementation of sepsis treatment programs improves outcomes including hospital length of stay and mortality.84,86 Variation and uncertainty exist in specific elements of ED care, particularly the optimal approaches to screening, diagnosis, fluid administration, and vasoactive therapy. Clinically, pediatric septic shock is identified by the presence of decreased perfusion or mental status in the setting of suspected infection.87

Pathophysiology

Shock represents the physiologic state of excess cellular oxygen demand for adenosine triphosphate (ATP). In septic shock, a pathogen initiates the shock state by triggering an inflammatory response in the host, and in toxin-mediated illness through direct effects on the host. The cytokine cascade promotes fever, leukocytosis, procoagulant effects, and increased vascular permeability.88 Deleterious consequences include endothelial cell damage, capillary leak, microcirculatory shutdown, and hypovolemic shock with decreased tissue oxygenation and mitochondrial dysfunction. The inflammatory immune response also causes vasodilation, myocardial depression, activation of the complement system, disseminated intravascular coagulation, and increased production of nitric oxide. Left unchecked, this inflammatory cascade progresses to end-organ hypoperfusion and multisystem organ failure.89

Infants and children with sepsis exhibit variability in their hemodynamic profile in sepsis. Studies using invasive and noninvasive monitoring to categorize hemodynamic patterns of fluid-refractory pediatric septic shock have shown that 40% to 60% of patients are in cold shock with decreased cardiac output. Marked by relative hypovolemia, vasoconstriction, and myocardial failure, this “cold” shock is more common in children than in adults. Half of all children in fluid-refractory shock will have mixed hemodynamics or vacillate between cold and warm shock (Table 163.4).90-92

Clinical Features

The diagnosis of sepsis begins with suspicion for infection, either fever or hypothermia, or an infectious presentation, such as pneumonia. When coupled with hypotension, this constitutes decompensated shock and should prompt immediate resuscitation. The emergency clinician should also begin resuscitation in the absence of hypotension when there are signs of decreased perfusion, including altered mental status, abnormal capillary refill time, abnormal pulse quality, or cold mottled extremities. Other concerning signs include seizure, loss of consciousness, and increased respiratory effort. These signs distinguished sepsis from other febrile illness in children hospitalized in the United Kingdom.93 The combination of hypotension and delayed capillary refill together portended the highest mortality in a large study of patients transported to a pediatric ICU (Fig. 163.2).94

Unfortunately, many of the recommended physical examination findings suffer from modest inter-rater reliability and low sensitivity, as well as low positive predictive value. No prediction

Note: Children frequently switch between categories, and repeated assessment of hemodynamics for adjustment of therapy is recommended.

**TABLE 163.4**

**Typical Patterns of Septic Shock Seen in Children**
rules or scores exist to optimize their use in ED diagnosis of compensated septic shock.\textsuperscript{94} Compounding this problem is that fever is among the most common chief complaints for children in an ED, often accompanied by tachycardia and tachypnea in non-septic patients. The diagnosis and treatment of pediatric septic shock is dependent on recognizing a syndrome of infection with decreased perfusion or altered mental status.

Laboratory testing and technologies to evaluate hemodynamics and vital signs show promise in sepsis diagnosis and monitoring but are not yet considered the standard of care.\textsuperscript{81} Risk stratification of patients may include serum lactate level, procalcitonin, B-natriuretic peptide, markers of coagulopathy or disseminated intravascular coagulation, and heart rate variability.\textsuperscript{95-98} Small studies suggest that, similar to adults, elevated serum lactate levels are associated with increased risk of organ dysfunction and death in children with sepsis. Although not an American Critical Care Medicine standard of care, we recommend that lactate levels be used in conjunction to the physical examination in diagnosing and monitoring treatment of pediatric septic shock. Risk-stratification strategies in a research setting include RNA expression profiling and novel serum biomarkers.\textsuperscript{99} These techniques hold promise in the future for more objective and systematic assessment to enable providers to distinguish children with more benign febrile illness from those with early septic shock.

Management

The pillars of emergency treatment of pediatric sepsis are timely establishment of intravascular access; rapid fluid resuscitation titrated to patient condition; appropriate, broad-spectrum antibiotics; and individualized vasoactive agents directed to reverse shock. Initial stabilization also includes recognition and correction of hypoxia, hypoglycemia, and hypocalcemia, to which children are particularly prone.\textsuperscript{82}

Timely and Appropriate Antibiotics

The Surviving Sepsis Campaign recommends antibiotic administration within 1 hour of recognition of septic shock.\textsuperscript{83} Delays in appropriate antimicrobial therapy increase mortality and prolong organ dysfunction in pediatric patients with severe sepsis or septic shock.\textsuperscript{100} Institutional antibiotic protocols can facilitate timely medication delivery; host factors, suspected source, and local susceptibility patterns should determine antibiotic selection.\textsuperscript{101}

Fluid Resuscitation

Septic shock in children is most frequently marked by relative or absolute hypovolemia; outcomes from shock in children are improved when the shock state is reversed as early as possible. Fluid should be administered using a “push-pull” inline syringe, rapid infuser, or pressure bag to achieve a goal of administering each 20 mL/kg crystalloid fluid bolus over 5 to 15 minutes, followed by reassessment and potentially additional boluses (Fig. 163.3). Fluid resuscitation should continue until vital signs and signs of perfusion improve. Concomitantly, patients should be monitored for signs of fluid overload. Continued shock after administration of 60 mL/kg of isotonic fluid bolus, or signs of fluid overload, such as presence of rales or hepatomegaly, should
be treated with vasoactive agents. We recommend that vasoactive agents be initiated in any pediatric patient with septic shock and hypotension lasting more than 1 hour, regardless of the amount of fluid delivered. In many patients in whom fluid resuscitation is achieved quickly, vasoactive agents may be required before 1 hour. Fluid status may be ascertained with clinical signs of shock, rales and hepatomegaly, as well as central venous oxygen saturation (SvO₂), bedside echocardiogram, serial serum lactate, and noninvasive cardiac output monitoring.

Cohort studies have demonstrated improved mortality and hospital length of stay in septic children with hypotension or organ dysfunction treated with 40 to 60 mL/kg of intravenous (IV) fluid in the first hour. However, a large randomized controlled trial in African children with severe infection, but not hypotension, demonstrated increased mortality in patients receiving 20 to 40 mL/kg in the first hour compared to no fluid. Although these results may be tied to the setting and large proportions of the study population with malaria and anemia, they have led to an increased focus on titrating IV fluid volume to the individual patient, and highlighted that IV fluid bolus should not be empirically given to every child with infection but not shock. Outcomes are similar for crystalloid versus colloid resuscitation, except in Dengue shock where colloid may lead to more rapid improvement.

Vasoactive Agents

Shock that persists despite fluid resuscitation should be treated with vasoactive agents. Dopamine, epinephrine, or norepinephrine may be used as a first-line agent in pediatric septic shock. Because the majority of children with septic shock have depressed cardiac output, dopamine or epinephrine is preferred due to their inotropic and peripheral vasoconstrictor effects. Dopamine has a long history of safety and efficacy in pediatric shock, but due to an association with increased risk of death in adult, epinephrine may be preferred. Norepinephrine is indicated for “warm shock” with high cardiac output.

Obtaining central venous access in an ill child is an uncommon procedure in most EDs, and it is a frequent source of delayed care in pediatric septic shock. We recommend rapid vascular access in critically ill children with peripheral IV catheters or an intraosseous device preferred for initial access. Vasoactive infusions can be administered through a peripheral IV catheter to correct shock until a central venous catheter can be safely placed. Hemodynamic Monitoring to Direct Therapy

In addition to the clinical examination, assessment of cardiovascular hemodynamics and choice of vasoactive agents can be enhanced by use of bedside echocardiography, as well as invasive and noninvasive cardiac output monitors. Studies that have used devices, including ultrasonic cardiac output monitor, bedside ultrasound, and pulmonary artery catheter, have demonstrated discrepancies between clinicians’ classification of hemodynamic states and those revealed by monitoring. Although no recommendations can be made at this time, these studies suggest that the customization of therapy aided by hemodynamic monitoring may direct emergency clinicians in their management.

In studies in Brazil and India, central venous oxygen monitoring to direct IV fluid resuscitation has been associated with improved mortality. SvO₂ should be titrated to 70% or more in patients with a central venous catheter.

Corticosteroids

Adrenal insufficiency in sepsis is moderately prevalent, but studies of hydrocortisone replacement in pediatric patients have yielded inconclusive results. There is insufficient evidence to support or refute the use of exogenous corticosteroids in children with sepsis, nor is there consensus on the optimal method of diagnosis of adrenal insufficiency. In children in shock despite epinephrine or norepinephrine infusion, testing of a serum cortisol level and administration of hydrocortisone may be considered in those at risk of adrenal insufficiency, including known abnormalities of the hypothalamic pituitary adrenal axis, chronic illness, chronic steroid use, and purpura fulminans.

Glucose

Although children with sepsis may be prone to stress hyperglycemia like adults, they are also prone to hypoglycemia due to their limited glycogen stores. Tight and conventional glycemic control has shown equivalence in critically ill children; a large trial is currently underway to determine optimal glucose-control strategies. We recommend correction of hypoglycemia when present, and cautious use of insulin and frequent glucose monitoring for blood glucose levels more than 180 mg/d.l.

Impact of Bundled Sepsis Care

Institutional quality improvement programs have improved timeliness and decreased variation in sepsis care. These programs decreased mortality and ICU and hospital length of stay. Institutional care delivery bundles for recognition, resuscitation, and performance measurement are recommended to optimize care.

ACUTE LIFE-THREATENING EVENTS

Principles

An acute life-threatening events (ALTEs) is “an episode that is frightening to the observer” and characterized by a combination of apnea, color change, change in tone, choking, or gagging. Typically these children are younger than 1 year old with the most common presenting age between 2 to 4 months old. Children with ALTEs pose a challenge, because the causes range from minor to life-threatening; and commonly a definitive etiology is not identified. In the minority of cases where an etiology is identified, it is most typically gastrointestinal reflux, seizures, or respiratory illness. More critical causes of ALTEs include non-accidental trauma, congenital heart disease, bacterial infection, and neurologic or metabolic abnormalities.

Clinical Features

The infant (<12 months old) with a history of an ALTE often appears well on presentation. Nearly 50% of children brought to the ED after an ALTE have an entirely normal clinical examina-
usual clinical judgment. Other testing should also be tailored to the child’s history and physical examination findings. Overall the highest yield tests, such as an upper gastrointestinal series, pertussis antigen, and pH probe, are not typically performed in the ED assuming close follow-up can be guaranteed and the patient undergoes a period of observation in the ED for 3 to 4 hours, to 

Disposition

High risk and ill-appearing infants should be admitted, as should infants with more than one episode of ALTE or those requiring resuscitation. Some patients with ALTE may be appropriate for discharge with close follow-up (Table 163.6). Otherwise healthy infants with their first episode, particularly when associated with feeding and a normal physical examination may be discharged assuming close follow-up can be guaranteed and the patient undergoes a period of observation in the ED for 3 to 4 hours, to ensure that there are no signs of progressive disease. Clinical prediction models have been derived but demonstrate imperfect sensitivity for poor outcomes and have not been validated.

The outcome of an ALTE depends on the underlying cause. The majority of ALTE studies with complete follow-up demonstrate no deaths.

---

**KEY CONCEPTS**

- Exact rates, depths, and ratios of compressions to ventilations in cardiopulmonary resuscitation (CPR) are not based on high quality evidence. It is most important to push fast, deep, and without interruptions. We recommend a depth of 1½ inches in infants and 2 inches in older children.
- Unlike in adults, conventional CPR versus compression-only CPR is recommended in most children, because children often arrest from respiratory causes. This is less important for the emergency department (ED) setting where compressions and ventilations should begin almost simultaneously.
- In pediatric arrest, timely acquisition of vascular access is much more important than the site of access; when access is needed, the intraosseous route is recommended.
- Central venous access is not required emergently in most pediatric arrests.
- The focus in pediatric cardiac arrest should be on providing high quality, uninterrupted compressions and ventilations, not medication administration.
- If defibrillation is indicated, begin at 2 J/kg, followed by 4 J/kg, and if needed increase to 10 J/kg for subsequent shocks.

- Unless specifically indicated, do not administer calcium or sodium bicarbonate in pediatric arrest of unknown cause.
- After return of circulation, focus on avoiding hypotension (intravenous [IV] fluids and vasoactive medications) and hyperthermia (antipyretics and cooling blankets).
- When death is likely, family presence at pediatric resuscitations provides significant lasting benefits for the family.
- There are no universal criteria to terminate resuscitation efforts in children. We recommend considering the termination of resuscitation after 30 minutes for unwitnessed out of hospital pediatric cardiac arrest.
- Due to the inherent risks associated with pediatric intubation, providers who lack extensive experience caring for critically ill children should focus on bag-mask ventilation, particularly for children in cardiac arrest or infants younger than 1 year old.
- Signs of sepsis overlap with the signs of many non-critical febrile illnesses in children.
- Treatment of pediatric sepsis in the United States should include rapid fluid boluses (total of 40 to 60 mL/kg for hypotension),

163.1. A 3-year-old girl presents to the emergency department (ED) with fever, lethargy, and a petechial rash. Her initial vital signs are: heart rate, 186 bpm; respiratory rate, 60 breaths per minute; blood pressure, 62/21 mm Hg; and pulse oximetry, 92% on room air. She is listless and ill appearing, with pale, cool extremities, and a capillary refill time of 4 to 5 seconds. After application of 100% oxygen and obtaining vascular access, what treatment should the patient receive next?

A. Calcium gluconate 50 to 100 mg/kg by intravenous push (IVP)
B. Ceftriaxone 100 mg/kg by rapid IVP
C. Dopamine at 5 to 10 mcg/kg/minute continuous infusion
D. Glucose 0.5 g/kg by rapid IVP
E. Normal saline 20 cc/kg by rapid IVP

Answer: E. Septic shock in children presents most commonly as a physiologic state of hypovolemia and increased systemic vascular resistance. Immediate and rapid isotonic crystalloid administration is the initial step for all children in shock.

163.2. All of the following are correct features of cardiopulmonary resuscitation (CPR) in children in cardiac arrest except:

A. Complete release of chest wall between chest compressions
B. Compression:ventilation rate of 15:2 once airway is secured with an endotracheal tube (ETT)
C. Depth of at least one-third the anteroposterior chest diameter
D. Rate of at least 100 compressions/minute
E. Use of a backboard under patient

Answer: B. In the intubated patient, compressions should be administered continually at a rate of at least 100/minute and ventilations continuously at a rate of 8 to 10 breaths/minute.

163.3. Which of the following statements best describes the practice of family presence in the emergency department (ED) for children?

A. Is not recommended; family presence sets up a medical legal minefield for the emergency clinician.
B. Is not recommended; providers perceive more stress, leading to clinical errors and family confusion.
C. Is recommended; although providers have been shown perceive more stress when parents are present, clinical care variables have not been shown to be impacted and families are more likely to effectively work through their grieving process.
D. Is recommended; providers do not perceive their presence, the grieving process is promoted, and clinical care variables are improved.

Answer: C. The American College of Emergency Physicians (ACEP) and American Academy of Pediatrics (AAP) recommend that family be given the option of being present during their child’s resuscitation. Families report their presence comforts their children, helps them appreciate the efforts of providers, facilitates their understanding of the gravity of the situation, and promotes the grieving process. Physicians reported increased stress from family presence, but no differences were detected in clinical care variables.
Neonatal Resuscitation

Ryan D. Kearney | Mark D. Lo

CHAPTER 164

PRINCIPLES

Approximately 10% of newborns require some assistance at birth, with 1% requiring extensive resuscitative measures. Knowledge of neonatal physiology, appropriate equipment, and procedural skills are essential to successful resuscitation. Preparation for neonatal resuscitation requires an understanding of how it differs from pediatric and adult resuscitation, primarily as follows:

1. Newborns have rapidly changing, dynamic cardiopulmonary physiology, with a unique range of normal vital signs.
2. Neonatal resuscitation is almost entirely respiratory (not cardiac) management.
3. Neonates require special and dedicated equipment.

PATHOPHYSIOLOGY

Transition From Fetal to Exouterine Life

The successful transition from fetal to extrauterine life requires three major cardiorespiratory changes: (1) removal of fluid from unexpanded alveoli to allow ventilation; (2) lung expansion and establishment of functional residual capacity; and (3) redistribution of cardiac output to provide lung perfusion. Failed development of adequate ventilation or perfusion leads to persistent shunting, hypoxia and, ultimately, a deleterious reversion to fetal physiology.

In utero, fetal nutrient and gas exchange is dependent on the placenta, a temporary organ with remarkably low vascular resistance, as well as the maternal circulation. As a result of its low resistance, the placenta receives approximately 30% of total fetal cardiac output between 18 and 41 weeks of gestation. In contrast, fluid-filled fetal alveoli have increased vascular resistance, leading to poor perfusion of the developing lung. The pulmonary arterial bed is so vasoconstricted that the fetal lung receives only 40% of right ventricular output and approximately 10% of total cardiac output; most of the right ventricular output is shunted from the pulmonary artery through the ductus arteriosus to the descending aorta. An additional right to left shunting occurs at the level of the foramen ovale, with relatively oxygen-rich blood shunted from the right to left atrium. Reversal of these two shunts is essential to the successful transition into extrauterine life and is facilitated by the significant drop in pulmonary vascular resistance that occurs at birth. The first step in this process is alveolar fluid clearance.

Removal of this fluid is partially accomplished by vaginal delivery, which provides some compression of the fluid out of the alveoli into the bronchi, trachea, and pulmonary capillary bed. The remaining fluid is largely evacuated by the first few breaths, with the quality of the first few breaths crucial to establishing adequate ventilation. Alveolar expansion requires the generation of high intrathoracic pressures and the presence of surfactant to maintain alveolar patency. Because the lung is one of the last organs to reach structural and functional maturity, interruptions in this coordinated physiologic process, although rare, should be nonetheless anticipated in all deliveries, particularly those outside of the delivery room.

After the first few breaths, pulmonary vascular resistance decreases as a result of alveolar oxygen exposure. Simultaneously, clamping of the umbilical cord removes the placenta from circulation, predictably increasing systemic vascular resistance. Shunting through the ductus arteriosus reverses as systemic vascular resistance increases; this usually ceases altogether by 15 hours of age as the ductus arteriosus also constricts. This reversal of flow redirects all right ventricular output to the lungs. However, hypoxia or acidosis can cause the pulmonary vascular bed to constrict again and, when severe or prolonged, recurrent pulmonary vascular constriction can cause the ductus arteriosus to reopen. The reinstatement of fetal circulation, with its attendant shunting, leads to ongoing hypoxia and is termed persistent fetal circulation. When indicated, resuscitation facilitates the first few breaths, prevents and reverses ongoing hypoxia and acidosis, and assists the newborn in the transition to extrauterine life.

INDICATIONS FOR RESUSCITATION

At least one person, whose exclusive role is to ensure safe transition of the newborn, should be present for all deliveries, including those that occur outside the delivery room. Any infant born outside of a delivery room should be anticipated to need resuscitation. Although minimal intervention may be required, a standardized approach should still be followed. Some specific conditions increase the likelihood that additional resuscitative efforts will be required.

Hypoxia

Even in the uncompromised newborn, it can take 10 minutes for blood oxygen saturation to reach normal extrauterine levels. Pulse oximetry may assist in determining hypoxemia, but it may take several minutes for a reliable waveform to be achieved. In utero or intrapartum asphyxia (pathologic lack of oxygen to the fetus before or during delivery) can precipitate a sequence of events that results in primary or secondary apnea. With initial hypoxia, rapid gasps are followed by cessation of respirations (primary apnea) and, if prolonged, decreased heart rate (HR). Ostensibly normal respiratory effort does not ensure adequate ventilation. However, bradycardia in the newborn (HR < 100 beats/min) almost always reflects inadequate ventilation and oxygenation. As such, bradycardia is a major indicator of hypoxia. Simple stimulation is required at the onset of primary apnea to stimulate ventilation and reverse bradycardia. If asphyxia persists, the newborn takes several final deep, gasping breaths, followed by cessation of respirations (secondary apnea); this is accompanied by worsening bradycardia, refractory to simple stimulation, and eventually hypotension. For new borns with secondary apnea,
more vigorous and prolonged resuscitation is needed to restore ventilation and adequate circulation.2

Hypothermia

Drying and warming the newborn are vital to initial resuscitation because the newborn's inability to maintain normothermia (>36.5°C [97.7°F]) has potentially dire consequences. Newborns cannot generate heat by shivering, cannot retain heat due to low fat stores, and have excess heat loss due to their large surface-to-volume ratio. Exacerbating these challenges in the immediate postpartum period, newborns have an acutely elevated metabolic rate, are covered with amniotic fluid, and are suddenly exposed to a relatively cool environment. Body temperature rapidly decreases, with hypothermia accelerating metabolic acidosis, oxygen consumption, hypoglycemia, and apnea.2,3 Prematurity and very low-birth-weight status exacerbate these consequences and require extra efforts to mitigate.3

Hypoglycemia

Poor glycogen stores, coupled with immature hepatic enzymes, place the normal newborn at increased risk for hypoglycemia. Hypoglycemia is particularly common in premature and small-for-gestational-age newborns, as well as those born to diabetic mothers. Hypoglycemia may also be a response to other factors, including respiratory illness, hypothermia, polycythemia, asphyxia, and sepsis. Hypoglycemia can be asymptomatic or may cause an array of symptoms, including apnea, color changes, respiratory distress, lethargy, jitteriness, seizures, acidosis, and poor myocardial contractility.9,10 A low blood glucose level, particularly when prolonged, recurrent, or associated with hyperinsulinemia, has been associated with adverse neurologic outcomes; correction of hypoglycemia, if detected expeditiously, improves outcomes.11 Neonatal hypoglycemia is generally defined as a blood glucose level less than 40 mg/dL, although this number serves as more of a guideline than a strict cutoff. All newborns exhibiting signs of hypoglycemia, with glucose levels less than 40 mg/dL, should receive intravenous (IV) glucose. Of note, bedside glucometers generally underestimate plasma glucose levels by approximately 10 mg/dL.10

Hypovolemia

Clinically significant hypovolemia is rare and usually secondary to blood loss. Risk factors include known maternal hemorrhage during delivery, prematurity, newborns with overt shock, and initiation of CPR.1,3,12 Hemorrhage can lead to respiratory depression and overt shock in the newborn, whether secondary to abruptio placentae, placenta previa, umbilical cord accident, or trauma. In the newborn, hemorrhage is one of the few situations in which fluid resuscitation and volume expansion improves outcomes. The following formula should be equivalent to gestational age in weeks:

Newborn mean arterial pressure (diastolic pressure + [pulse pressure/3])

where pulse pressure = systolic pressure − diastolic pressure. Examination findings consistent with hypovolemia or hemodynamically significant hemorrhage include pallor, despite oxygenation, weak pulses with a rapid HR, and poor response to resuscitation.1,3,12

Prematurity

Premature infants, especially those born before 34 weeks of gestational age, are uniquely at risk due to their pulmonary immaturity and susceptibility to hypothermia. Those requiring delivery room cardiopulmonary resuscitation (CPR) have increased risk of mortality, bronchopulmonary dysplasia, severe brain injury, pneumothorax, and intestinal perforation.13 For these reasons, in utero transfer of high-risk pregnant women to tertiary centers possessing expertise and experience with premature infant resuscitation has been associated with improved neonatal outcomes.14 Intubation should be performed for the premature newborn in respiratory distress, which is clinically suggested by retractions, desaturation, or tachypnea.15 In certain cases, surfactant may be delivered via an endotracheal tube (ETT) shortly after birth.

Meconium-Stained Amniotic Fluid

Meconium-stained amniotic fluid (MSAF) indicates potentially significant newborn stress prior to delivery. Aspiration of meconium and its consequences can be avoided, or at least significantly limited, by rapid intervention. Previous recommendations stipulated suctioning meconium from the newborn’s airway after delivery of the head but before delivery of the shoulders (intrapartum suctioning). However, there appears to be no benefit from intrapartum suctioning.16,17 Therefore, current recommendations no longer advise routine intrapartum suctioning of newborns with MSAF. To prevent aspiration of meconium, previous recommendations also stipulated tracheal suctioning of all nonvigorous newborn with MSAF immediately on delivery and before any other resuscitative efforts (including drying and stimulation). However, routine endotracheal intubation in nonvigor and vigorous term, meconium-stained newborns has shown no benefit, including the incidence of meconium aspiration syndrome (MAS), pneumothorax, oxygen need, stridor, seizure, or hypoxic ischemic encephalopathy.18 Standard measures to support adequate ventilation and oxygenation should be initiated for all infants born through MSAF, with a small subset eventually requiring endotracheal intubation, as warranted.3

The most recent recommendations from the American Heart Association have changed the practice of tracheal suctioning after delivery for meconium aspiration. Indications for intubation in newborns born through MSAF are the same as those for all neonates; meconium aspiration should only be performed if indicated for signs of airway obstruction secondary to meconium that do not improve despite standard resuscitative measures, including warming and drying and initiation of effective positive-pressure ventilation (PPV). When performing tracheal suctioning, a meconium aspirator (Fig. 164.1) should be attached to the appropriately sized ETT and connected to wall suction at 100 mm Hg or less. On intubation by direct laryngoscopy, the ETT is then withdrawn while suction is applied. Serial re-intubation with suctioning should be repeated to remove obstructing meconium or until the infant becomes vigorous, which is usually accomplished after two rounds. If bradycardia or apnea persists beyond two passes, ongoing resuscitation should include bag-mask ventilation (BMV) and consideration of endotracheal intubation to secure

Fig. 164.1. Meconium aspirator with suction and 3.0 uncuffed ETT attached. (Courtesy Seattle Children’s Hospital, Seattle, WA.)
the airway. In tertiary centers with skilled providers, lung lavage with dilute surfactant may be beneficial, particularly if prolonged intubation appears inevitable.19

Maternal Factors

Infection

Maternal infection (chorioamnionitis) is a particularly common trigger for premature delivery; premature infants are themselves more susceptible to infection. Therefore, IV antibiotics should be administered after obtaining blood cultures and a complete blood count should be carried out in all infants born before 37 weeks of gestation.

Medications

Medications provided to the mother during labor or illicit drugs taken before delivery, usually opioids, can augment newborn respiratory depression. Maternal opioid administration or antenatal drug abuse should be considered in any newborn with isolated respiratory depression that persists, despite a seemingly successful initial resuscitation. As in adults, opioid-induced respiratory depression could be reversed with naloxone.1,21 However, naloxone may precipitate acute withdrawal and seizures in the newborn of an opioid-dependent mother; thus, naloxone is not recommended in the initial resuscitation of the newborn.21 Suspected opiate toxicity in the newborn should be treated with support of oxygenation and ventilation rather than pharmacological reversal. This should include use of a bag-mask device and, if necessary, intubation.

Withholding and Discontinuing Resuscitation

No reliable and widely adopted set of parameters has been identified for newborns who should not receive resuscitative efforts.23 Resuscitation is not currently recommended for neonates with a confirmed gestational age less than 23 weeks, those with birth weight less than 400 g, and those with confirmed anencephaly, trisomy 13, or trisomy 18.23,24 Parental request has been shown to be the most important factor determining resuscitative efforts for newborns at 22 to 25 weeks of gestation; most neonatologists consider a gestational age more than 25 weeks of gestation to be the most important factor determining resuscitative efforts. Most newborns with a 10-minute APGAR score of zero,27 highlighting the importance of dialogue with the parent(s) and acknowledgment of their feelings regarding the risks of morbidity. Parents should actively participate in the decision to continue or withdraw resuscitative efforts in cases in which there is prognostic uncertainty. For infants with a low 10-minute APGAR score but some signs of life, especially when aligned with parental preference, resuscitation efforts should continue until further prognostication can occur.

SPECIAL ANATOMIC ANOMALIES

Diaphragmatic Hernia

In addition to pulmonary hypoplasia, neonates with diaphragmatic hernias have exquisitely reactive pulmonary vascular beds, predisposing them to potentially fatal pulmonary vasospasm in the immediate and late postnatal period.28 Examination findings concerning for congenital diaphragmatic hernia include barrel chest, ipsilateral absence of breath sounds, tracheal or point of maximum cardiac impulse displacement, and scaphoid abdomen. Bag-mask ventilation will distend the stomach, which is usually intrathoracic, further worsening respiratory distress. The neonate should be emergently intubated if a prenatal diagnosis of diaphragmatic hernia is known or if a diaphragmatic hernia is diagnosed on the chest radiograph (Fig. 164.2).

Myelomeningocele and Omphalocele

Infants with myelomeningocele should never be placed supine but instead be placed prone or on the side to avoid pressure on the defect. Resuscitation should proceed from this modified position (Fig. 164.3). For unclear reasons, myelomeningocele is associated with an elevated risk for latex allergy, necessitating efforts to avoid latex sensitization in these neonates.24 The spinal defect should be gently wrapped with sterile gauze pads soaked in warm sterile saline and enclosed with plastic wrap.30 Infants with gastroschisis or omphalocele should be resuscitated as needed, and these defects should also be covered with an occlusive plastic wrapping to decrease water and heat loss.31 These newborns often require parenteral maintenance fluid infusion, orogastric tube for gastric decompression, and antimicrobial prophylaxis with IV antibiotics.23

Choanal Atresia

Because newborns are obligate nose breathers, bilateral choanal atresia causes upper airway obstruction and often severe respiratory distress. Choanal atresia can be rapidly diagnosed by the
inability to pass a catheter through either naris into the posterior oropharynx. An oral airway device can bypass the obstruction. Special attention should be paid to initial the physical examination of these children because these infants often have a multiple congenital anomaly syndrome.

Pierre Robin Sequence

The hallmark of this abnormality is profound micrognathia, resulting in glossoptosis (retraction or downward displacement of the tongue) and cleft palate. Pierre Robin sequence, therefore, confers a high risk for significant upper airway obstruction. A nasal or oral airway should be able to bypass the obstruction; if not, intubation may be necessary. Given the technical challenges of performing endotracheal intubation on a patient with Pierre Robin sequence, fiberoptic intubation is often needed, although prone positioning and a laryngeal mask airway (LMA) or other supraglottic airway device can be attempted to support ventilation. Consultation with anesthesiology or otolaryngology may be required.

Congenital Cardiac Disease

Echocardiographic evidence of congenital heart disease (CHD) is as high as 5% for term newborns. However, critical CHD, defined as requiring surgery or catheter-based intervention in the first year of life, accounts for only up to 50% of CHD cases. Stereotypic examination findings seen in critical CHD include a blood pressure gradient between the upper and lower extremities, weak femoral pulses, central cyanosis, pathologic murmur, and hepatomegaly. These signs of cardiogenic shock in a newborn may be fairly indistinguishable from those of severe sepsis and respiratory failure. Resuscitation of a newborn with known or suspected critical CHD should therefore include standard ventilatory management, as well as empiric antimicrobial therapy. Cardiomegaly on a chest radiograph is more likely consistent with cardiogenic shock. Some common laboratory findings include polycythemia and unexplained acidosis. Many newborns with critical CHD have a ductal-dependent lesion and are likely to experience profound physiologic decompensation—defined by severe metabolic acidosis, seizure, cardiac arrest, or renal or hepatic injury—on closure of the ductus arteriosus. Prostaglandin E1 (PGE1) should be used in lesions with ductal-dependent systemic or pulmonary blood flow (Box 164.1). In case of an uncertain diagnosis or in preparation for transport to a specialized facility, prostaglandin should be started via continuous IV infusion. A second peripheral IV is recommended to treat the possible adverse effects of prostaglandin, including hypotension, tachycardia, and apnea. Continuous PGE1 should begin soon after birth, with gradual dose titration to a maximum of 0.1 µg/kg/min. For a more in-depth discussion on CHD, see Chapter 170.

PREPARATION

To maximize the effectiveness of resuscitation, all emergency departments should have an age- and weight-appropriate prestocked drug pack, standardized equipment (Box 164.2), and staff trained on newborn resuscitation. The pediatric length-based resuscitation tape (Broselow Luten tape) can be used to determine equipment size and drug dosages for newborn resuscitation of infants weighing 3 kg or more. A dedicated neonatal resuscitation cart, organized according to the Neonatal Resuscitation Program (NRP) algorithm, increases the speed of equipment retrieval and is preferred by providers to other organizing schemes. When available, additional maternal information (Box 164.3) can help anticipate resuscitation needs so that appropriate staff, equipment and disposition plans can be expeditiously managed.

Universal precautions, including gown, gloves, and eye protection, should be followed during neonatal resuscitations. An
MANAGEMENT

As part of their shared NRP curriculum, the American Heart Association and American Academy of Pediatrics, with the International Liaison Committee On Resuscitation, have developed a newborn resuscitation algorithm (Fig. 164.5). This stepwise approach is detailed below. However, if a term neonate is crying and appears to have good tone, she or he can be warmed, dried, and returned to the mother for ongoing care and evaluation, without any additional resuscitation efforts.

Newborn Resuscitation Algorithm

Dry, Warm, Position, Suction, Stimulate, and Assess Need for Further Intervention

Hypothermia increases metabolic demand and oxygen consumption, which can render seemingly effective resuscitation efforts futile. To prevent these and more subtle sequelae of hypothermia, all newborns should be dried immediately on delivery and placed under a radiant heat source. In the case of crying term infants with normal tone, this may be accomplished by simple drying and skin to skin contact with the mother. Wet blankets should be replaced with dry blankets and preferably warm linens, but the baby should be left uncovered to facilitate radiant warming and team access, when required. All resuscitation techniques are designed to be performed with these temperature-controlling efforts in place. The supine neonate should be further positioned to maximize air entry and avoid obstruction of airflow. Due to a relatively large occiput and anterior glottic opening, airway patency is best achieved with the neck in slight extension. A slightly extended position that aligns the posterior pharynx, larynx, and trachea is best accomplished by placing a rolled diaper or small towel under the infant's shoulders. Placement under the neck is not useful. However, a towel that is too large and under the shoulders can also lead to airway occlusion due to hyperextension of the neck.

Only if meconium is present and the newborn has poor tone, poor respiratory effort, or bradycardia (HR < 100 beats/min) after 1 minute of appropriate PPV should the trachea be suctioned with an ETT and meconium aspirator attachment. Poor respiratory effort and obvious obstruction from secretions should otherwise be treated with bulb or mechanical suction (~100 mm Hg wall suction). Upper airway suctioning, including that performed with a bulb syringe, should be reserved only for newborns with these signs because suctioning has been associated with decreased lung compliance, bradycardia, and lowered cerebral blood flow velocity. In one randomized study comparing NRP-recommended bulb suctioning versus mouth wiping, there were no differences in mean respiratory rate, use of advanced resuscitation efforts, Apgar scores, neonatal intensive care unit (NICU) admission, and discharge oxygen saturation levels. When suction is indicated, the NRP protocol should be followed, with the mouth suctioned first, followed by the nose. This sequence helps avoid aspiration of oral secretions if the neonate inspires after nasal suctioning. Overly vigorous or deep suctioning should be avoided because it can cause significant vagal stimulation and subsequent bradycardia or apnea. Because NRP recommendations stipulate suctioning with less than 100 mm Hg, emergency clinicians should be judicious with syringe use because even standard delivery bulb syringes produce a modest negative pressure, which easily exceed this threshold.

For most term neonates, these measures stimulate breathing sufficiently and may be all that is required to resuscitate a newborn. If adequate respirations are still not present, additional stimulation should be given. This is best done by flicking the soles of the feet and rubbing the back; more aggressive efforts could prove

external heat source should be turned on early and the table warmed prior to the start of resuscitation. Hypothermia is an independent risk factor for neonatal mortality worldwide. Similarly, hyperthermia is an effect modifier of neonatal encephalopathy and correlates with respiratory depression, cerebral palsy, and mortality. Correct equipment size is essential; in particular, respiratory supplies are most likely to be used and are key to most resuscitative efforts. Appropriately sized self-inflating devices (Fig. 164.4) decrease complications from overventilation, prevent injury, and limit the inability to ventilate due to improper mask fit. When available, and in the hands of experienced providers, flow-inflating devices have the added ability to deliver continuous positive airway pressure (CPAP), control ventilation pressure with greater precision, and ensure a proper fit. Table 164.1 lists the recommended ETT sizes by birth weight and gestational age.

Maternal History Questions

1. What is the estimated gestational age?
2. Is this a multiple gestation?
3. Is meconium present?
4. Is there a history of vaginal bleeding?
5. Were medications given or drugs taken?
6. Was there documented maternal fever?
7. Did mother have routine prenatal care? If so, were any abnormalities seen on prenatal ultrasonography?
harmful. If stimulation and warming efforts prove inadequate, PPV is required, followed by intubation, if necessary.

Time is an important component of NRP guidelines. Within the first 60 seconds of life, the newborn should be assessed with simultaneous warming, drying, and stimulation; if necessary, upper airway clearance should be performed (see Fig. 164.5). If the HR is below 100 beats/min, or if the newborn has primary apnea or respiratory distress, PPV and pulse oximetry should be initiated within the first minute of life. If bradycardia (HR < 60 beats/min) persists, despite adequate ventilation, chest compressions should be initiated. HR calculation can be manual—by palpation of the pulse at the base of the umbilical or auscultation

© 2015 American Heart Association

of cardiac sounds—with pulse oximetry, or with a standard electrocardiographic lead. Persistent bradycardia is usually secondary to inadequate ventilation. Thus, intubation is recommended in the event that chest compressions are indicated.

 Routinely counted at 1, 5, and 10 minutes of life, the APGAR score (Table 164.2) is a composite that reflects HR, respiratory effort, muscle tone, reflex irritability, and color. The score is primarily for assessing the need for (1 minute) and efficacy of (5 minute) ongoing resuscitative measures. In the setting of modern algorithm-based resuscitation, low 5- and 10-minute APGAR scores are associated with increased mortality because they identify infants who are failing medical management. Muscle tone and reflex irritability do not significantly aid in the assessment of the newborn during resuscitation. Instead, HR and respiratory effort are the important indicators and should be continuously monitored. Skin color is a poor indicator of oxyhemoglobin saturation during the first several minutes of life while the transition from fetal to infant circulation ensues. In this brief period, pulse oximetry may be a useful tool to assess the oxygenation status of the newborn. NRP guidelines specify pulse oximeter use only in a few select situations—anticipated resuscitation, prolonged PPV use, persistent cyanosis, and use of supplemental oxygen.

### Ventilation, Oxygen, Intubation

Any neonate with persistent cyanosis or signs of respiratory distress (eg, grunting, nasal flaring, tachypnea) should be assisted by CPAP or PPV. For apnea, severe respiratory distress, or an HR less than 100 beats/min, BMV (with a manometer, if available) should be initiated. The first breaths often require higher pressures (30–40 mm Hg) to remove lung fluid, with the adequacy of ventilation assessed by chest rise. An initial sustained breath of 2 to 5 seconds may further increase functional residual capacity (FRC) and promote clearance of lung fluid, but several clinical trials have yet to prove the efficacy and safety of this technique. Subsequent breaths generally require 20 mm Hg of peak inspiratory pressure. To minimize barotrauma and the incidence of pneumothorax, excessive pressures (defined as more than needed to achieve adequate chest rise) should be avoided. An appropriately sized mask with a tight seal (covering the mouth and nose, but not the eyes), proper positioning of the newborn, and use of pressure to attain correct chest wall movement are essential for effective ventilation. Unless otherwise dictated by blood gas levels, recommended ventilation rates are 40 to 60 breaths/min, aimed at achieving a heart rate above 100 beat/min. Current NRP guidelines recommend PPV, but do not delineate between CPAP and PEEP (positive end-expiratory pressure). However, preterm neonates (<33 weeks' gestation) receiving single-inflation CPAP (pressure-controlled inflation at 20 cm H₂O for 10 seconds) appear less likely to be intubated at 72 hours of age, receive more than one dose of surfactant, or develop bronchopulmonary dysplasia (BPD). When BMV is required for more than 2 minutes, an orogastric tube should be placed to prevent respiratory compromise from gastric distention.

Resuscitation with 100% oxygen is no longer recommended. There appears to be reduced mortality in infants resuscitated with room air, with no obvious evidence of harm. There is increased oxidative stress, including direct cardiac and renal injury. Neurologic outcomes appear improved by resuscitation with room air versus 100% oxygen, likely due to a reduction in cerebral free radical generation. Current NRP guidelines recommend initiating resuscitation with room air and then blending to increasing oxygen concentrations, as needed. Use of 100% oxygen for resuscitation should occur only if the newborn has persistent bradycardia below 60 beats/min bradycardia after 90 seconds. Attempts to restore adequate ventilation are more beneficial than increasing the oxygen concentration. There has been a growing body of literature suggesting that lower initial preductal oxygen saturation in healthy uncomplicated newborns may contribute to the appearance of cyanosis; oxygen saturation after birth may not reach 90% or more until 10 minutes of life.

Endotracheal intubation is indicated at several points during neonatal resuscitation—tracheal suctioning for meconium in infants with failure to improve, despite effective PPV; if BMV is ineffective or prolonged; when chest compressions are performed; and for extremely low-birth-weight infants or infants with anatomic anomalies (eg, diaphragmatic hernia). Traditional direct laryngoscopy and videolaryngoscopy are both reasonable options, with video-assisted techniques consistently having improved views but slightly longer total intubation times. Confirmation of proper ETT placement should include detection of expired carbon dioxide. Although ultrasonography can show appropriate ETT positioning in term and preterm infants, the gold standard remains plain radiography.

If acute deterioration occurs shortly after intubation, equipment must be immediately checked. Consider the DOPE and MR SOPA mnemonics when trying to determine the cause of the deterioration (Box 164.4). In the absence of an obvious explanation, it is safest to extubate the newborn and promptly ventilate with a BMV device by an experienced provider. Needle aspiration

of the chest may be considered for treatment of a possible pneumothorax, particularly if unequal breath sounds are appreciated upon extubation, ventilatory pressures are inexplicably high, or a neonate’s condition fails to improve with effective ventilation.

If ETT intubation is indicated but is technically challenging, the LMA has been shown to be effective for ventilating full-term newborns. However, there are limited data on LMA use in preterm infants (<2000 g or <34 weeks’ gestation), in the setting of MAS or during cardiopulmonary resuscitation (CPR).

Chest Compressions

Bradycardia (HR < 100 beats/min) is a reliable indicator of clinically significant hypoxia. Fortunately, most neonates with bradycardia respond promptly to effective ventilation. If a neonate has an HR less than 60 beats/min, despite oxygen and adequate ventilation (good air movement and chest rise) for at least 30 seconds, chest compression should be started. Compressions should be performed at a rate of 90/min, coordinated with 30 breaths/min for a total of 120 events/min. The preferred neonatal resuscitation compression-to-ventilation ratio is 3:1. If the provider is certain that the cardiac arrest has a primary cardiac cause, a compression-to-ventilation ratio of 15:2 may be considered. The preferred method for performing chest compressions, the two thumb-encircling hands technique, is as follows: the fingers of both hands encircle the chest and support the back, with the thumbs of both hands placed side by side or one on the other on the sternum, just below the nipple line. The depth of compression is one-third the anteroposterior diameter of the chest. Spontaneous respirations and HR should be assessed every 30 seconds, attempting to minimize interruptions, when possible, with coordinated chest compressions and ventilation continuing until the HR is at least 60 beats/min. A yellow color change on a colorimetric CO2 monitor during PPV administration often precedes a significant rise in HR and should be used, when available.

Medications

Few neonates require pharmacotherapy during resuscitation. Medications (Table 164.3) are primarily indicated for bradycardia or asystole unresponsive to effective ventilation and chest compressions, as well as hemorrhage (maternal, fetal, or placental) that necessitates fluid resuscitation.

Vascular Access

The umbilical vein is the preferred route of immediate vascular access because it can be easily identified and cannulated. Umbilical vein access can have serious complications (eg, infection, portal vein thrombosis), so the umbilical vein cannula (UVC) should be removed by the accepting neonatologist after the infant has been stabilized and additional venous access has been obtained. Other vascular access routes include peripheral veins, peripherally inserted central catheters, and the femoral vein. Intraosseous (IO) access can be problematic in neonates (especially premature infants) because of bone fragility and the small size of the intraosseous space. However, in simulated resuscitation, placement of an IO line has been shown to be almost 1 minute faster than a UVC, even for skilled providers. Preferred IO access sites in newborns include the proximal tibia (≈2 cm below the tuberosity and 1 cm medially on the tibial plateau) and distal femur (midline; ≈1 cm above the superior border of the patella, with the leg in extension). If vascular access cannot be achieved, certain drugs including epinephrine, can be given through the ETT, although this is not the optimal route.

Types

Epinephrine. Epinephrine is indicated for asystole and persistent bradycardia less than 60 beats/min despite effective ventilation with 100% oxygen and ongoing coordinated chest compressions. Although it may be given by ETT, the preferred epinephrine administration route is the IV route. The recommended IV dose is 0.01 to 0.03 mg/kg, or 0.1 to 0.3 mL/kg, of a 1:10,000 solution. Unlike epinephrine use in adult patients, weight-based dosing with no known minimum is required for neonates. Repeat doses may be given every 3 to 5 minutes. If administered via an ETT, higher doses (0.05–0.1 mg/kg) with a 1:10,000 solution are indicated, but the safety and efficacy of this practice have not been rigorously evaluated.
adult resuscitations, sodium bicarbonate is not routinely used, although it may be beneficial in the NICU setting when ventilation is known to be adequate.\textsuperscript{17,19}

**Volume Expanders.** When indicated, volume expansion is accomplished with packed red blood cells (Rh-negative type O blood), normal saline or Ringer’s Lactate solution given in IV boluses of 10 mL/kg over 5 to 10 minutes. During resuscitation of premature infants, rapid administration of volume expanders should be avoided because this practice has been associated with increased incidence of intraventricular hemorrhage.\textsuperscript{20} Higher volume (eg, 20 mL/kg) fluid boluses are recommended for full-term infants. Boluses may be repeated several times, as indicated by the ongoing response to resuscitative efforts.

**Antibiotics.** Antibiotics are not indicated in the initial resuscitation phase, but may be required once the neonate has been stabilized. When suspected, sepsis should be treated aggressively with broad-spectrum antimicrobial therapy directed against the most likely pathogens. The most common bacterial pathogens implicated in early-onset neonatal sepsis are a heterogeneous group that includes group B Streptococcus (GBS), Escherichia coli, Klebsiella spp., Enterobacter spp., and Listeria. In the United States, where GBS and E. coli represent the most common newborn pathogens, a recommended empirical antibiotic regimen is ampicillin (100 mg/kg IV) plus an aminoglycoside (usually gentamicin, 4 mg/kg).\textsuperscript{19} Reasonable alternative regimens include ampicillin with a third-generation cephalosporin, but there is evidence that several members of the latter group predispose a neonate to invasive candidiasis. Because ceftriaxone can increase the risk of kernicterus, cefotaxime (50 mg/kg IV) is preferred.\textsuperscript{19}

**Glucose.** Concomitant hypoglycemia should be considered and promptly treated in a neonate requiring ongoing resuscitation. Hypoglycemia is most easily diagnosed by rapid bedside glucose testing or serum glucose level measurement. Neonates with a glucose level less than 40 mg/dL and with symptoms of hypoglycemia—irritability, tremors, jitteriness, apnea, tachypnea, seizures, cyanosis, lethargy, poor feeding—require treatment with IV glucose. Standard therapy is 2 mL of 10% dextrose in water (D\textsubscript{10}W)/kg as well as starting a continuous infusion of D\textsubscript{10}W at 80 to 100 mL/kg/day.\textsuperscript{21,22} Higher concentrations of glucose (eg, 25% dextrose in water, D\textsubscript{25}W) are hyperosmolar and should be avoided. If the newborn can safely tolerate feeds, oral glucose solution, maternal breast milk, or formula should be given by mouth (PO) on demand. Repeat glucose measurement should be obtained 10 to 20 minutes after glucose administration. Asymptomatic neonates with hypoglycemia should be encouraged to feed more often and are treated with IV glucose only if glucose levels fall precipitously (<25 mg/dL at birth to 4 hours of age or <35 mg/dL at 4–24 hours of age).\textsuperscript{19}

**Dopamine.** Dopamine is indicated only when signs of shock (eg, poor peripheral perfusion, weak pulses) are still present, despite adequate volume replacement. Given as a continuous infusion beginning at 5 µg/kg/min, dopamine may be increased to 20 µg/kg/min as necessary, before additional inotrope support is indicated.

**Therapeutic Hypothermia**

When moderate to severe hypoxic-ischemic encephalopathy is suspected, selective cerebral hypothermia in asphyxiated infants may protect against brain injury.\textsuperscript{1,81-89} Therapeutic hypothermia of 33.5° to 34.5°C (92.3°–94.1°F) in this population can lower mortality and improve the likelihood of normal neurologic outcome at 18 months. Current NRP guidelines recommend therapeutic hypothermia for patients with suspected early neonatal asphyxia. Symptoms of possible evolving brain injury include abnormal levels of consciousness, seizures, hypotonia, and hyporeflexia.\textsuperscript{20} Established protocols generally recommended the initiation of cooling within 6 hours of birth, for a total of 72 hours, followed by gradual rewarming over at least 4 hours. Neonates meeting eligibility criteria should be transferred to facilities capable of providing this specialized care. Emergency clinicians and families should be aware that the risks associated with therapeutic hypothermia include thrombocytopenia and hypotension.\textsuperscript{81-86}

**DISPOSITION**

Early consultation with a neonatologist can assist in the resuscitation and postresuscitation phases of care. Once a neonate is stabilized, the monitoring of oxygenation, ventilation, perfusion, temperature, and glucose level continues. Neonates who require extensive resuscitation (ie, obtaining venous access, medication requirement, and/or endotracheal intubation) should be transported to an NICU by personnel skilled in neonatal resuscitation. If feasible and safe, parents should be allowed to see, touch, and hold the newborn before transport.

**OUTCOMES**

**Safety**

Advanced life support skills are critical for successful neonatal resuscitation, yet are far from routine for most emergency clinicians. For example, in a cohort of almost 5000 births at a tertiary level hospital, only 30 infants required intubation, 15 were given chest compressions, and only 10 received epinephrine or volume expanders.\textsuperscript{90} An important step toward improving outcomes is team adherence to NRP guidelines. Highlighting the importance of safety, an essential component of the new NRP curriculum is the inclusion of simulation.\textsuperscript{91} Simulation in neonatal resuscitation allows for a multidisciplinary team to practice behavioral and teamwork skills, not only individual technical skills, in a safe environment. Implementation of an integrated TeamSTEPPS (Team Strategies and Tools to Enhance Performance and Patient Safety) and NRP curriculum has been shown to result improved outcomes in regard not only to communication, but also to incorrect medication dosing and inadequate chest compression depth.\textsuperscript{92} Furthermore, routine (and unannounced) simulation-based neonatal resuscitation training has been shown to improve provider self-confidence in addition to knowledge and technical and nontechnical skills.\textsuperscript{92}

**Effectiveness**

In the hands of trained emergency clinicians, neonates requiring advanced resuscitative efforts receive improved PPV, decreased time to vascular access, and shortened time to first IV medication.\textsuperscript{94} Deliberate training of emergency medicine residents has been shown to result in double their self-rated confidence scores and improved ability to perform the key first steps of resuscitation—dry, warm, position, stimulate.\textsuperscript{95} These dramatic provider level improvements are seen worldwide with the implementation of guideline-based care. For patients, the results are just as profound. For example, implementing neonatal resuscitation practice protocols at county-level hospitals in China has been shown to decrease birth asphyxia from 8.8% to 6.0% and asphyxia-related deaths from 27.6 to 5.0/100,000.\textsuperscript{96} Early analyses of the NRP program, which has now trained more than 5 million providers in the United States alone, have suggested that fewer high-risk infants experience a drop in APGAR score from 1 to 5 minutes, with many actually showing an improvement since
Further Considerations

The need for chest compressions and CPR is a known prognostic marker for increased rates of morbidity and mortality in neonates. Undergoing CPR at delivery increases the likelihood of pneumothorax, grades 3 and 4 intraventricular hemorrhage, bronchopulmonary dysplasia, and death by 12 hours and 120 days after birth.\(^{100}\) Unfortunately, these complications have also been associated with long-term neurodevelopment impairment (NDI), with less than 15% of infants with 5-minute APGAR scores lower than 2 surviving without NDI.\(^{100}\) The implementation of a local neonatal resuscitation protocol appears to improve neurodevelopment outcome; follow-up data have suggested that the incidence of electroencephalographic abnormalities, cerebral palsy, and seizure disorders are all greatly reduced.\(^{101}\)

**KEY CONCEPTS**

- Resuscitation should be anticipated for all neonates born outside the delivery room; 10% of newborns will require some resuscitation, and 1% will require advanced life support interventions after birth.
- Predictable indications for resuscitation include hypoxia, hypothermia, hypoglycemia, hypovolemia, prematurity, maternal infection, and adverse effects of maternal medication.
- Drying, warming, positioning, and stimulating the infant are sufficient resuscitative measures for most deliveries.
- Adequate ventilation will reverse most bradycardia whereas, in general, 100% oxygen is not indicated for most neonatal resuscitations.
- The NRP resuscitation algorithm provides a proven guide for management and its implementation has shown to improve short- and long-term outcomes, including neurodevelopment.
- Routine tracheal suctioning of vigorous and nonvigorous infants born through meconium-stained amniotic fluid is no longer recommended.
- Weight-based epinephrine and volume expanders are rarely required.
- Significant hypovolemia is rare in neonates. Hemorrhage is one of the few predictable situations in which volume expansion improves newborn outcome.
- Preterm infants and those born to mothers with suspected infection, including chorioamnionitis, should receive empirical antibiotic therapy. An acceptable regimen includes dual therapy with ampicillin and gentamicin.
- Any neonate with persistent cyanosis or signs of respiratory distress (eg, grunting, nasal flaring, tachypnea) should be assisted by CPAP or PPV. Endotracheal intubation should be performed in several situations, such as when bag-mask ventilation is ineffective or prolonged, chest compressions are performed, an extremely low-birth-weight infant is born, and tracheal suctioning for meconium in infants results in failure to improve, despite effective PPV.
- Chest compressions are rarely required because bradycardia generally responds to effective ventilation. However, compressions should be started for an HR less than 60 beats/min, despite oxygen and adequate ventilation for 30 seconds.
- The umbilical vein is the preferred route of immediate vascular access, followed by peripheral veins, peripherally inserted central catheter lines, and the femoral vein. IO line placement can be problematic in neonates.
- No reliable and widely adopted set of parameters has been identified for newborns who should not receive resuscitative efforts. Unless there is clear family, parent, and/or health care provider agreement, all resuscitation efforts should continue until further prognostication can occur.
- Infants receiving appropriate resuscitation efforts nonetheless showing no signs of life after 10 minutes may have further efforts withheld, particularly when this decision is in accord with parental preference.
- All newborns requiring IV placement, medication administration, chest compressions or endotracheal intubation should be transferred to an appropriate neonatal intensive care unit.

CHAPTER 164: QUESTIONS & ANSWERS

164.1. With most neonatal deliveries, which resuscitative measures are usually sufficient?
- A. Administer fluids.
- B. Administer glucose.
- C. Bag-mask ventilate.
- D. Intubate.
- E. Warm, dry, stimulate, and position.

Answer: E. Drying, warming, positioning, and stimulating the infant are usually sufficient resuscitative measures in most deliveries.

164.2. For a newborn with cyanosis, respiratory distress and a heart rate more than 100 beats/min, which of the following is not initially indicated?
- A. Apply 100% oxygen.
- B. Position airway.
- C. Suction.
- D. Ventilate with bag-mask with room air.
- E. Warm, dry, and stimulate.

Answer: A. 100% oxygen is no longer indicated for initial resuscitation; avoiding unnecessary supplemental oxygen is thought to minimize free radical creation in the brain and decreases the incidence of retinopathy of prematurity. Initial resuscitation with room air is recommended.

164.3. In a typical neonatal resuscitation, what is the preferred compression-to-ventilation ratio?
- A. 3:1
- B. 5:1
- C. 10:2
- D. 15:2
- E. 30:2

Answer: A. Unlike pediatric or adult cardiopulmonary resuscitation (CPR), neonatal CPR is performed at a ratio of three compressions to one breath, with a goal of approximately 90 compressions with 30 synchronized breaths (120 “events”) per minute. If the cause of the bradycardia is known to be cardiac, a ratio of 15:2 is acceptable.

164.4. A nonvigorous and crying newborn is delivered with copious meconium-stained fluid. What is the correct recommended resuscitative measure?
- A. Bag-mask ventilate.
- B. Intubate.
- C. Intubate and suction.
- D. Suction at maternal perineum before cutting umbilical cord.
- E. Gentle mouth suctioning if needed, followed by warming, drying, and stimulation.

Answer: E. For infants born with meconium-stained amniotic fluid, routine intubation and endotracheal tube suctioning are no longer recommended because they have shown no consistent benefit. Vigorous and nonvigorous infants born through even thick meconium should instead have gentle mouth suctioning, if needed, followed by warming, drying, and stimulation.

164.5. After drying, stimulating, and bag-mask ventilation, what is the next step in resuscitation of a newborn that appears floppy and apneic and with a heart rate of 50 beats/min?
- A. Give a normal saline bolus of 20 mL/kg.
- B. Give epinephrine (1:10,000) intravenous (IV) at a dose of 0.1 mg/kg.
- C. Intubate.
- D. Start with a chest compression-to-ventilation ratio of 3:1.
- E. Suction.

Answer: D. With a heart rate less than 60 beats/min in a neonate, intubation may be considered, but compressions should be started. If the low heart rate persists, IV epinephrine (1:10,000) may be considered at a dose of 0.01 mg/kg.
PRINCIPLES
Trauma is the leading cause of death among children from 1 to 18 years old in the United States, with injuries accounting for more than 8 million annual emergency department (ED) visits. Head injury is the most common cause of pediatric trauma deaths. Motor vehicle collisions (MVCs) account for more than half of all pediatric trauma deaths, whereas nonfatal injuries are primarily due to falls. Other nonfatal injuries vary by age. Young children (<4 years old) experience higher rates of animal bites and burns. School-age children (5 to 9 years old) are more likely to experience bicycle and pedestrian injuries. Older children (>9 years old) have high incidences of both fatal and nonfatal motor vehicle–related trauma and higher incidences of suicide and self-inflicted harm.

Anatomy and Physiology
Children have distinctive anatomy and unique physiology that impacts the evaluation and management of the pediatric trauma patient (Box 165.1). Force is more widely distributed through the body of a child, making multi-system injuries more likely in children. The younger a patient is, the greater their surface area to weight ratio, resulting in a greater potential for heat loss. Even mild to moderate hypothermia contributes to metabolic acidemia and has direct negative effects on cardiac inotropy, chronotropy, catecholamine responsiveness, platelet function, and drug clearance through both renal and hepatic routes. Therefore, maintenance fluid requirements, oxygen extraction and consumption, and glucose utilization are much higher per kilogram in infants and small children than in adults.

A child’s physiologic response to injury is different from an adult’s, depending on the age and maturation of the child and the severity of the injury. Children have a great capacity to maintain blood pressure despite significant acute blood losses constituting up to 30% of total blood volume. A child’s cardiac output is primarily determined by the heart rate and systemic vascular resistance. Compensated shock should be considered and promptly addressed when a child’s heart rate is elevated, especially if the capillary refill time is delayed. Changes in heart rate, blood pressure, and extremity perfusion commonly precede cardiopulmonary failure and should be recognized and resuscitation initiated.

CLINICAL FEATURES

Initial Assessment Priorities and Primary Survey
The highest priority is ruling out the presence of life- or limb-threatening injuries. Treatment of these injuries precedes continuation of the physical examination. This initial assessment and necessary initial resuscitation efforts occur simultaneously. In general, the assessment and resuscitation phase of the evaluation should be addressed within the first 5 to 10 minutes. Any child with a potentially serious or unstable injury should have continual reassessment. The elements of the primary survey for pediatric trauma patients can be remembered by A, B, C, D, E, and F.

A—Airway and Cervical Spine Stabilization
Chapter 161 describes anatomic considerations that have implications in the management of the pediatric airway. Possible airway obstruction or inability of the child to maintain his or her own airway should be assessed. Spinal motion restriction should be maintained with significant mechanisms, increased risk of spinal injury with trauma (eg, Down syndrome), or signs of neurological injury post trauma. (Evaluation of the cervical spine in children is discussed later in this chapter.) The airway can be opened with a jaw-thrust maneuver. Gurgling or stridor may indicate upper airway obstruction. Maxillofacial trauma, loose teeth, blood, swelling, or vomitus may obstruct the airway, and efforts should be made toward clearing the oropharynx of debris. If an open airway cannot be maintained by noninvasive means, endotracheal intubation (ETI) will be required.

Indications for ETI in a pediatric trauma patient may include (1) inability to ventilate with bag-mask ventilation (BMV) or the need for prolonged control of the airway, (2) Glasgow Coma Score (GCS) of less than 9, (3) respiratory failure from hypoxemia or hypoventilation, and (4) the presence of compensated shock resistant to initial fluid administration. Box 165.2 lists airway equipment sizes.

B—Breathing and Ventilation
Breath sounds and adequacy of chest rise should be assessed. In a young child, this rise occurs in the lower chest and upper abdomen. Both the chest and the abdomen should move concordantly. Discordant motion is referred to as paradoxical breathing and is a sign of impending respiratory failure. Respiratory rates that are too fast or too slow can also indicate impending respiratory failure; treatment is assisted ventilation. If assisted ventilation is necessary, BMV should be initiated. Only the volume necessary to cause the chest to rise should be provided. Excessive volume or rate of ventilation can lead to gastric distention (increasing the risk of vomiting and aspiration), which may lead to respiratory embarrassment and potential hypotension caused by decreased venous return and impaired diaphragmatic function. Gastric decompression may be performed in children who are intubated with an orogastric or, when deemed appropriate, a nasogastric tube.

Many factors may compromise ventilatory function in an injured child. These include depressed sensorium, occlusion of the airway, painful restriction of lung expansion, diaphragmatic fatigue, and direct pulmonary injury. Adequate ventilation is dependent upon airway patency and sufficient air exchange. Pulse oximetry measures adequacy of oxygenation but not ventilation. Continuous end-tidal carbon dioxide capnography can better inform ventilatory status. Table 165.1 describes priorities in the assessment of breathing in pediatric trauma patients.
**Box 165.1**

**Specific Anatomic Differences in Adults and Children: Implications for Pediatric Trauma Management**

The child’s head-to-body ratio is greater, the brain is less myelinated, and cranial bones are thinner, resulting in more serious head injury. The child’s internal organs are more susceptible to injury based on more anterior placement of liver and spleen, and less protective musculature and subcutaneous tissue mass. The child’s kidney is less well protected and more mobile, making it susceptible to deceleration injury. The elasticity of the child’s chest wall allows for pulmonary injury without skeletal injury. Growth plates are not yet closed in pediatric patients, leading to Salter-type fractures with possible resultant limb-length abnormalities. Children have a more tenuous spinal cord blood supply and a greater elasticity of the vertebral column, predisposing them to spinal cord injury without radiographic abnormality (SCIWORA).

**Box 165.2**

**Equipment Size Estimates for Pediatric Trauma**

**Endotracheal Tube Size Estimates (Sizing in Millimeters Internal Diameter) and Depth**

For children 1 to 10 years old, a length-based resuscitation tape may be used, or ETT size can be estimated by the following formulas:

- Cuffed endotracheal tube size (mm) = (Age in years/4) + 3.5
- Uncuffed endotracheal tube size (mm) = (Age in years/4) + 4

An ETT 0.5 mm larger and 0.5 mm smaller in internal diameter should also be ready at the bedside.

Depth of ETT (cm) = (tube size) × 3

**Largest Chest Tube Size**

Largest chest tube diameter = 4 × the endotracheal tube size

**Orogastric, Nasogastric, or Foley Size**

Orogastric, nasogastric, or Foley diameter = 2 × ETT size

**Femoral Line Sizing Estimates (Weight Based)**

- ≥3 kg = 3 F
- 3–10 kg = 4 F
- 10–20 kg = 5 F
- >20 kg = 6 F

**Box 165.3**

**Circulation Assessment and Treatment in Critical Pediatric Trauma Patients**

**Assessment**

Increased heart rate, slow capillary refill, decreased peripheral pulses, and altered sensorium may indicate poor circulation. Vital signs should be monitored every 5 minutes during the initial assessment. Continuous oximeter and cardiac monitor.

**Treatment and Interventions for Hypovolemic Shock from Trauma**

Place two large-bore IV lines (above and below diaphragm when indicated). Consider central line or intravenous line placement if peripheral venous access is difficult. Bolus with 20 mL/kg of warmed normal saline, and repeat if necessary. Consider intubation and ventilation to decrease work of breathing. Transfuse 10 to 20 mL/kg PRBC for compensated shock secondary to blood loss.

**IV**, Intravenous; **PRBC**, packed red blood cells.

**Box 165.4**

**Disability Assessment**

For assessment of patient disability, a rapid neurologic and mental status evaluation is needed. The assessment of disability in pediatric trauma patients is described in **Box 165.4**. The alert, verbal,
painful, unresponsive (AVPU) system (Box 165.5) and the modified pediatric GCS (Table 165.2) are useful to the emergency clinician to assess level of consciousness as well as motor strength.

E—Events, Exposure, and Thorough Examination

The historical details of the trauma as well as initial response to the event are key to estimation of risk of injury. Type of force applied, secondary impacts, such as being struck and then ejected from a vehicle or thrown onto the ground, response to the trauma (ie, loss of consciousness, seizure, altered level of consciousness), and initial interventions by emergency medical service (EMS) personnel as applicable.

The trauma patient should be fully undressed to assess for hidden trauma. However, patients should also be kept normothermic, because metabolic needs are greatly increased by hypothermia. The environment of care for pediatric trauma patients should

Disability: Neurologic Assessment and Treatment

**ASSESSMENT**
Level of consciousness: Use AVPU scale and age-appropriate Glasgow Coma Scale
Pupil size and reactivity
Extremity movement and tone
Posturing and reflexes

**TREATMENT AND INTERVENTIONS**
Stabilize spinal column with spinal motion restriction techniques.
If GCS <9: RSI.
If altered mental status, obtain a head CT scan and neurosurgical consultation as needed.
With signs of herniation, consider 3% hypertonic saline 6.5–10 mL/kg IV (or mannitol 0.25 to 0.5 g/kg IV), if possible elevate the head of the bed, keep the facing forward, and hyperventilate to a PCO2 of 30 to 35 mm Hg.
Maintain CPP of at least 50 mm Hg in children and 70 mm Hg in adults.
Assess for signs of spinal injury, including respiratory failure and bulbocavernous reflex or presence of anal wink.

have an increased ambient temperature, and warmed humidified oxygen, warmed fluids, and warmed blood should be used to avoid heat loss as is possible. Head wraps, and convective warmers or radiant heat sources should be used as soon as possible in newborns and infants, as well as older children when their temperature is 95°F (35°C) or lower. The exposure phase of the survey is often the appropriate time to concurrently begin imaging and further diagnostic testing (Table 165.3).

F—FAST and Family

The focused assessment with sonography in trauma (FAST) evaluates for traumatic free fluid in the peritoneum and pericardial space and has proved to be useful in children. In hemodynamically unstable children, a FAST may point to hemorrhage in the abdomen or the pericardial space and the need for intervention. In hemodynamically stable children, the FAST examination may indicate the need for computed tomography (CT) imaging, closer observation, repeat abdominal examinations, or repeat ultrasound examinations. The extended FAST (eFAST) examination incorporates the addition of lung views to evaluate for pneumothorax or hemothorax.

In the management of children, the family (caregivers) may be added to the primary survey, to remind emergency clinicians to rapidly inform the family of the evaluation and progress and assess their concerns. Allowing family members to be present during resuscitations is acceptable and often preferred by families. Some family members choose not to be present, but they should have the choice. We recommend having a staff member dedicated to the family during the resuscitation: to explain treatments, answer questions, and provide emotional support.

Secondary Survey

After completion of the primary survey and requisite procedures, the secondary survey is performed. The secondary survey is an organized, complete assessment to detect additional injury. A more complete history and examination are obtained. Features of the history that need to be obtained can be remembered by the mnemonic AMPLE (Box 165.6). Ongoing assessment of the patient occurs after the secondary survey, and key points are summarized in Box 165.7.

MANAGEMENT AND DIAGNOSTIC TESTING

General Management Principles

In most cases of pediatric trauma, the child is stable and evaluation can proceed without need for intravenous (IV) access or laboratory evaluation. In pediatric patients who have sustained major trauma, they should be placed on cardiac and pulse oximetry monitoring, receive supplemental oxygen, and have continuous reassessment of vital signs. Vascular access is best obtained by accessing the upper extremity for the establishment of two large-bore IV lines. In the absence of available upper extremity peripheral sites, lower extremity sites may be used. Many emergency clinicians favor the femoral vein as a safe site for insertion of a central line; preferably under ultrasound guidance (see Box 165.2).

If vascular access is unobtainable or delayed, intraosseous access is a safe, quick, and reliable procedure to access the vascular space. Although most commonly started in the proximal medial tibia just below the growth plate, intraosseous access can be obtained in the proximal humerus, the flattened area of the anterior distal femur, the distal tibia, or even the sternum. Once intraosseous access is obtained, it should be stabilized and secured to ensure it is not accidentally displaced. More than one intraosseous needle may need to be placed (in separate bones), and IV access may be more easily inserted once fluids have been given. Intraosseous placement in a fractured extremity is contraindicated. Medications and blood products can be administered through an intraosseous line.

Other less commonly used vascular access techniques for trauma include venous cut-down and umbilical vein cannulation for neonates. Venous cutdown is a skill not often performed by emergency clinicians and is rarely needed to obtain vascular access in the pediatric trauma patient. If performed, the greater

| Full examination      | Fully undress.
|                       | Look under collar and splints.
|                       | Log roll and examine back.
|                       | Perform rectal examination if indicated. |
| Imaging               | Consider chest and pelvis radiographs. |
|                       | Consider additional imaging of any area of pain or trauma. |
|                       | Perform a bedside FAST examination. |
| Laboratory            | Complete blood cell count, type and crossmatch, urinalysis, urine pregnancy test, urine drug screen. |
| Supportive interventions | For pelvic fracture, consider binding to decrease pelvic volume and aid hemostasis. |
|                       | For extremity fractures, consider reduction and splinting. |
|                       | Place urinary catheter and nasogastric or orogastric tube as indicated. |
| Medications           | Provide analgesia with IV medications. |
|                       | Tetanus vaccine and tetanus immune globulin for appropriate cases. |
|                       | Antibiotics when indicated. |

FAST: Focused assessment with sonography in trauma; IV: intravenous.
saphenous vein at the ankle is the preferred site. Umbilical vein cannulation can be achieved in infants up to approximately 7 to 10 days old, as long as there is enough of an umbilical stump to perform the procedure.

Most hypovolemic pediatric trauma patients respond to 20 mL/kg boluses of isotonic crystalloids. If 40 mL/kg has not reversed systemic signs of hypoperfusion, an additional 20 mL/kg bolus of crystalloid may be given, and an infusion of packed red blood cells (PRBCs) at 10 mL/kg should be given while investigating for potential sources of shock. In patients in decompensated hemorrhagic shock or cardiopulmonary failure secondary to hemorrhage, crystalloid and blood products should be administered simultaneously. With massive transfusion (blood product volume of ≥40 mL/kg), it is important to add platelets to correct coagulopathy.2 We recommend plasma, platelets, and PRBCs given in a near 1:1:1 ratio if massive transfusion is expected. This is based predominantly on adult studies.2,6

In trauma, shock is most likely hemorrhagic in nature. Cardiogenic shock is rare. However, chest trauma associated with shock should alert the emergency clinician to the possibility of concomitant tension pneumothorax, myocardial injury, or pericardial tamponade. Neurogenic and spinal shock can also occur in traumatic injury and are discussed later in this chapter.

Physical Examination

After the primary survey, a head-to-toe examination is carefully performed. Specifics of the head examination include inspection and palpation of the skull and facial bones, assessment of pupil size and reactivity, and evaluation of extraocular movements. A funduscopic examination may be considered in cases of possible nonaccidental trauma. A fluorescein examination may reveal occult eye injury. Eye shields (not patches) should be used to protect eyes with possible globe rupture.

Assessment of the cervical spine is done carefully. The patient should be removed from the backboard with spinal motion restriction maintained if not clinically cleared or if at high risk for cervical spine injury. Backboards cause pain and with time skin breakdown at pressure points and should be removed as quickly as possible. There are no common indications to justify leaving children on backboards after their initial evaluation. When the patient is rolled to remove the backboard, palpation of the rest of the spine can take place with an emphasis on evaluating for ecchymosis, tenderness, and step-offs. Obtunded patients and those with signs or symptoms of thoracic or lumbar spine injuries should be carefully moved and positioned to protect them from possible further injury until imaging or return of consciousness allows for definitive assessment.

Assessment of the chest and internal structures involves inspection for wounds and flail segments; palpation for tenderness, crepitus, and point of maximal cardiac impulse; and auscultation for asymmetry or abnormal breath sounds.

The abdominal examination consists of inspection, palpation, and a FAST examination. A “seat belt sign” across the abdomen is a sign of potential serious traumatic injury. Palpation is best done on a cooperative patient but is an insensitive screening test for the presence of an injury.

A digital rectal examination should only be performed when its result has a reasonable chance of changing the patient’s treatment.10 It may provide information on sphincter tone in possible spinal injury and the presence of blood in penetrating trauma but otherwise we recommend it not be done routinely.

Although urethral injury is rare in children, all trauma patients should be assessed for perineal, scrotal, penile, or lower abdominal hematoma and blood at the urethral meatus. If there is concern for urethral injury, a retrograde urethrogram should be completed before the insertion of a urinary catheter.

Extremity examination evaluates for deformities, penetrations, neurologic deficits, and interruptions of perfusion. Fractures may be stabilized with splinting prior to definitive management. Careful and recurrent (especially after interventions such as splinting or reduction) vascular and neurologic examinations should be performed in all cases of extremity injury.

Reexamination of trauma patients throughout their time in the ED is important to ensure that their condition has not changed, that their pain is controlled, and that no injuries are overlooked. Ambulation as appropriate prior to discharge is helpful in uncovering additional injuries identified with previous examinations. Up to 70% of injuries with delayed diagnosis in pediatric trauma are orthopedic in nature.7

Pain Control

Pain control is an essential part of any trauma patient’s management. Analgesic medications, immobilization of injured extremities, and nonpharmacologic techniques should all be considered. Please refer to Chapter 162.

Diagnostic Testing

Laboratory Studies

Blood sampling for a pediatric trauma patient is no different than that for an adult trauma patient; however, use of smaller blood collection tubes may be necessary in infants and small children.

In hypovolemic shock, hemoglobin alone is unreliable because equilibration will not have occurred at the time of presentation to the ED. Serial hemoglobin measurements may be useful to assess the possibility of ongoing bleeding.8

Children’s glucose utilization and metabolic rate per kilogram are much greater than those of adults. Any child with a change in mental status after trauma should have a point of care glucose level checked immediately. Any child requiring dextrose owing to hypoglycemia will likely need an ongoing dextrose supply to prevent recurrence of hypoglycemia.

Older pediatric trauma patients should be assessed for substance abuse and depression as contributing factors to the traumatic event. Post-pubertal females or those girls Tanner stage 3 or greater should be tested for pregnancy.

Radiology

Chest and pelvic radiographs can assess for causes of respiratory failure, sites of blood loss, and causes of shock. In stable, alert children without distracting injuries, the pelvic film may be eliminated if no suggestion of sacral or pelvic fracture is found on thorough clinical examination.12 Plain pelvic films have been shown to have limited sensitivity in children after blunt trauma.13 In children with pelvic or sacral tenderness and negative plain radiographs, a CT scan should be strongly considered.

Other imaging is obtained based on the physical examination. For patients sustaining minor trauma, no imaging may be needed. Evaluation of suspected nonaccidental trauma is discussed in detail in Chapter 177.

SPECIFIC DISORDERS AND INJURIES

Head Injury

Principles

Traumatic brain injury is the leading cause of death and disability in children older than 1 year old in the United States.14-16 Infants and toddlers are more prone to falls from their own height,
school-age children are involved in sports injuries and MVCs, and children of all ages are subject to the sequelae of abuse.

Important anatomic variations lead to differences in pediatric and adult head trauma. The cranial vault of a child is larger and heavier in proportion to the total body mass. This predisposes young children to high degrees of torque that are generated by forces along the cervical spine axis. Sutures within the pediatric skull are both protective and detrimental to the outcome of head injury. Although the cranium may be more pliable relative to traumatic insult, forces are generated internally that predispose the pediatric patient to parenchymal injury in the absence of skull fractures. The pediatric brain is less myelinated, with higher water content, predisposing it to shearing forces, further injury, and post-traumatic seizures.

Clinical Features

The mechanism of the head injury relates to the severity of injury. The height of the fall and the quality of the surface at the point of impact are particularly important with regard to the development of associated injury. Most children fall from their own height, and impact with an object increases the localized force even after a short fall. In MVCs, the type of restraint that was present at the time of the collision should be evaluated because unrestrained and improperly restrained children are more prone to serious injury.

It is also important to establish if alteration of consciousness occurred at the time of the injury event. The behavior of a child after a traumatic event should be assessed with questions related to the presence or absence of irritability, lethargy, personality change, or other alterations in behavior. The prognostic significance of vomiting after pediatric head trauma is unclear. Recurrent vomiting is commonly seen in patients with significant head injury and is often considered in the decision to obtain a CT study; however, in the case of isolated vomiting without other clinical signs, a period of observation is an option.

A brief seizure that occurs immediately after an insult (with rapid return to normal level of consciousness) is commonly called an *impact seizure*. The decision to scan should take into account the mechanism of injury and current neurologic status of the

---

**Fig. 165.1.** Head injury rule chart. AMS, Altered mental status; CT, computed tomography; GCS, Glasgow Coma Score; LOC, loss of consciousness; MVA, motor vehicle collision.
child, but in most cases a CT scan is performed for post-traumatic seizure. If a CT scan is not performed, a period of observation for at least 2 hours in the ED is prudent. Seizures that occur later (more than 20 minutes after the insult) herald a greater possibility of traumatic brain injury and the development of seizures at a later date. A CT scan is indicated for these later post-traumatic seizures. These patients may benefit from treatment with anticonvulsants as having one later seizure (nonimpact) raises the risk of subsequent additional seizures. Seizures also raise ICP, while often decreasing oxygenation and ventilation.

The examination of a head-injured child include strict attention to the ABCs (airway, breathing, and circulation). Because the pediatric brain is sensitive to decreases in oxygen, perfusion, and glucose, their maintenance reduces further brain insult and optimizes the chances of good recovery. Cerebral perfusion pressure (CPP) is adequate only in the face of a normal mean arterial pressure (MAP). Conceptually, CPP is equal to MAP minus ICP:

\[
CPP = MAP - ICP
\]

As MAP is reduced, so is CPP. Localized CPP at the site of injury and in the areas surrounding it may vary greatly from this formula’s approximations. Pediatric patients with any form of head injury should have an evaluation of their cervical spine for injury.

Several methods are available for evaluating the mental status of head-injured patients, including the AVPU system and the GCS. A commonly used modification of the GCS for children is shown in Table 165.2. A child with a head injury should have cranial nerve, motor, sensory, cerebellar, reflex, and memory testing. The most important aspect of motor and cranial nerve evaluation involves ruling out the presence of increased ICP. Common symptoms and signs of increased ICP in infants and children should be sought (Boxes 165.8 and 165.9).

### Differential Diagnoses

**Concussion.** A concussion is a functional brain injury seen after a blow to the head or body, a fall, or another injury that shakes the brain within the skull. Radiographic studies should be obtained if there are symptoms suggestive of intracranial hemorrhage. In concussions, structural radiographic studies are normal. Patients who sustain concussive insults may have somatic, cognitive, affective, and sleep symptoms. All children with concussive symptoms should be monitored for progression of symptoms by their primary care physician or a concussion recovery specialist. They should undergo both physical and cognitive rest until symptoms have resolved, then return slowly to their baseline activities.

**Scalp Injuries.** Bleeding from scalp wounds is often profuse and can lead to hemodynamic compromise in infants and small children if not quickly controlled. Scalp injuries in infants and children may also involve the development of three injury complexes. For these injury complexes to be better understood, the layers of the skin, connective tissue, aponeurosis, loose areolar tissue, and periosteum (SCALP) should be considered (Fig. 165.2). *Caput succedaneum* refers to a hematoma in the connective tissue layer. This is freely mobile and crosses suture lines. A *subgaleal hematoma* refers to a hematoma that is subgaleal within the loose areolar tissue above the periosteum. Lastly, *cephalocele* refers to a collection of blood under the periosteum. Because the periosteum adheres tightly to the various suture lines, the cephalocele does not cross them.

**Skull Fractures.** In children, skull fractures occur in many different configurations. Simple linear non-depressed fractures rarely require therapy and often are associated with good outcomes. Factors associated with poor outcomes include the presence of a fracture overlying a vascular channel (especially the middle meningeal artery), a depressed fracture, or a diastatic fracture. Diastatic fractures, or defects extending through suture lines, are different from simple linear fractures in that leptomeningeal cysts (“growing fractures”) may develop at these sites. Leptomeningeal cysts are more common in children younger than 3 years old and are the result of a dural tear and skull fracture. In “growing fractures,” the leptomeninges herniate through the dural tear, causing bony erosion around the fracture site. The presence of cerebrospinal fluid rhinorrhea and otorrhea has been associated with fractures of the skull base. Signs of basilar skull fractures in children are similar to signs in adults and include the presence of periorbital subcutaneous hematoma (raccoon eyes) and posterior auricular ecchymosis (Battle sign). It should be noted that these signs can take hours to days to develop, and therefore absence of these signs cannot rule out basilar skull fractures.

### Box 165.8

**Symptoms and Signs of Increased Intracranial Pressure in Infants**

- Full fontanel
- Split sutures
- Altered level of consciousness
- Paradoxical irritability
- Persistent emesis
- “Setting sun” sign (bilatera downward gaze of the eyes with apparent inability to elevate the eyes superiorly in a normal manner leading to an area of sclera being seen between the iris and the upper palpebra)

### Box 165.9

**Symptoms and Signs of Increased Intracranial Pressure in Infants and Children**

- Headache
- Stiff neck
- Photophobia
- Altered state of consciousness
- Persistent emesis
- Cranial nerve involvement
- Papilledema
- Hypertension, bradycardia, and hypoventilation
- Decorticate or decerebrate posturing

---

*From Neurosurgical Knowledge and Practice, Volpe and Shintaku, 3rd edition.*
Cerebral Contusions. Cerebral contusions are often the result of coup and contrecoup forces. Cerebral contusions may not be associated with any loss of consciousness at the time of insult. Patients often have associated symptoms, such as altered level of consciousness, severe headache, vomiting, or focal deficits on neurologic assessment. Contusions are clearly demonstrable on CT.

Epidural Hematoma. Epidural hematomas are typically caused by bleeding from the meningeal vessels and often associated with overlying fractures. Traditional teaching regarding the development of epidural hematomas involves the typical triad of head injury followed by a lucid interval, followed by rapid deterioration as intracranial hemorrhage worsens. After head trauma, guardians are informed of the delayed signs and symptoms that should prompt immediate reassessment.

Subdural Hematoma. Subdural hematomas are often secondary to the rupture of bridging veins. Less than half of pediatric cases have overlying fractures. Subdural hematomas most commonly occur in patients younger than 2 years old. Chronic subdural hematomas are associated with “shaken baby syndrome.” This clinical complex involves forcible shaking of the child with accelerating and decelerating forces affecting the cranial vault. This syndrome is most often a result of nonaccidental trauma. Subdural hematomas at multiple sites, over areas other than the convexities, in the posterior fossa, or in the posterior interhemispheric fissure should suggest the possibility of nonaccidental trauma. These patients have nonspecific findings, such as vomiting, failure to thrive, change in level of consciousness, or seizures. See Chapter 177 for a more in-depth discussion on nonaccidental trauma.

Diagnostic Testing and Management

Serial examinations are the most reliable indicators of clinical deterioration. The presence of focal findings on neurologic examination is a reliable indicator of a localized insult, whereas the absence of focality may be misleading. The classic Cushing response (bradycardia and hypertension) does not always occur in children; but when it occurs, it is often an ominous sign. If ICP elevation is suspected, emergency intervention and neurosurgical consultation are immediately warranted (Table 165.4).

The contents of the skull are composed of three main compartments: brain, cerebrospinal fluid, and blood. Because the cranial vault is a fixed volume, the Monroe-Kellie doctrine suggests the effects that changes within each compartment may have on the others. For example, in the presence of an intracerebral hemorrhage of significant volume, either cerebral spinal fluid or brain must leave the cranial vault. Similarly, if the brain swells, cerebral spinal fluid, blood, or both must leave the cranial vault. When this balance is disrupted and the autoregulatory system’s capacity to adapt is exceeded, the ICP rapidly increases. ICP can quickly reach a level that is not conducive to localized brain survival or continued blood flow to the brain. If the condition is left untreated, herniation may occur.

BP, blood pressure; CBF, cerebral blood flow; CPP, cerebral perfusion pressure; ED, emergency department; ICP, intracranial pressure; IV, intravenously; MAP, mean arterial pressure; PaCO₂, arterial carbon dioxide partial pressure.
Most emergency clinicians favor early and controlled intubation in pediatric trauma patients with GCSs that are deteriorating or are less than 9. For the out-of-hospital phase of care, BMV ventilation is recommended over intubation for support of ventilation and oxygenation. Isolated head injury is uncommon; a careful search for other injuries should be made.

The use of anticonvulsants after moderate to severe head injury in children is controversial. Early prophylaxis does not decrease the incidence of late seizures and is not recommended for this purpose. However, because early seizures after trauma are discordant with the management principles of acute brain injury, some guidelines suggest the use of prophylactic anticonvulsants (most often phenytoin or levetiracetam). These decisions should be made in consultation with the neurosurgical service. If a seizure does occur, aggressive management is necessary.

Herniation syndromes in children are similar to those in adults. These are described in Chapter 34. Management of suspected acute herniation begins with immediate controlled hyperventilation. Clinical endpoints of hyperventilation are improved patient status or constriction of dilated pupils. Subsequent management of herniation includes hyperosmolar agents, (mannitol or hypertonic saline) followed by other specific interventions in the intensive care unit (ICU).

**Radiology**

**Skull Radiographs.** Possible indications for skull radiographs include the skeletal survey involved with the evaluation of child abuse, establishment of a functioning ventricular peritoneal shunt, some penetrating wounds of the scalp, or the suspicion of foreign bodies underlying scalp lacerations. In children requiring neuroimaging because of concern for intracranial injury, a noncontrast CT scan is the recommended test, because plain skull radiography lacks sufficient sensitivity to be used as a screening tool. A recent retrospective cross-sectional study calls into question the necessity of admission for otherwise neurologically normal children with isolated skull fractures and no concern for nonintentional trauma, because the cost is high and the incidence of neurosurgical intervention in these patients seems very low. In selected cases after neurosurgical consultation, discharge with close outpatient follow-up and return precautions may be acceptable.

**Computed Tomography of the Head.** There has been a considerable amount of research on the indications and relative value of CT scanning in pediatric head-injured patients. CT of the head when appropriately used can be lifesaving and of small individual risk even to children who generally have higher risk than adults due to higher radiation sensitivity, higher likelihood of future imaging studies, longer life expectancy, and the still prevalent higher than necessary radiation dose used for pediatric studies. Although based on extrapolations of data from atomic bomb related cancers, it is generally accepted that the lifetime risk of cancer to an individual due to a CT scan is on the order of one in 500 to 1000. Studies have shown various combinations of characteristics that make significant intracranial injury very unlikely but have provided less guidance in the selection of which patients actually need a head CT scan (high negative predictive value but low positive predictive value).

As children of different ages manifest intracranial trauma differently, guidelines on CT imaging are age-based. In infants, suspicion of abuse should trigger strong consideration for head CT imaging if signs and symptoms warrant it. For children younger than 2 years old, head CT imaging should be performed in the presence of altered mental status, GCS of 14 or lower, or a palpable skull fracture. In the same age group, occipital, parietal or temporal scalp hematomas, a history of loss of consciousness 5 seconds or more, not acting normally per parent, or a severe mechanism of injury should lead to a period of observation in the ED or head CT. Children older than 2 years old with GCS of 14 or lower, altered mental status, or signs of basilar skull fracture should undergo head CT imaging. A history of loss of consciousness, vomiting, severe headache or severe mechanism of injury should prompt observation or a head CT.

All children who sustain head injury, with or without diagnostic imaging, should be monitored closely for any signs of deterioration. Those with intracranial injury should be admitted to the hospital and seen by the neurosurgery service. Most patients with normal brain CTs or with isolated linear skull fractures in the setting of minor blunt head trauma who have a normal GCS, a stable examination, and no focal neurologic signs may be discharged home. Reliable caretakers should be given specific return precautions for any focal deficit, lethargy, worsening of symptoms, or alteration of consciousness.

**Spinal Injury**

**Principles**

Spinal cord injury patterns vary with the age of the patient. Although cervical spinal injuries are less common in children than in adults, higher cord level injuries are more common in children and can lead to devastating outcomes. Fractures above the C3 level account for the majority of cervical spinal lesions in children younger than 8 years old, which differs dramatically from the patterns seen in older children and adults. Anatomic features of the cervical spine approach adult patterns between 8 and 10 years old (Box 165.10). However, injury patterns identical to those of adults often do not fully manifest until 15 years old.

**BOX 165.10**

**Anatomic Differences in the Pediatric Cervical Spine**

Cervical spine fulcrum changes from C2 to C3 in toddlers to C5 to C6 by 8 to 12 years old.

Relatively larger head size, resulting in greater flexion and extension injuries.

Relatively large occiput in children younger than 2 years old leads to flexion of cervical spine if they are laid flat on standard backboard without support under their scapula and pelvis.

Smaller neck muscle mass with ligamentous injuries more common than fractures.

Anterior wedge appearance of cervical vertebral bodies is common.

Increased flexibility of interspinous ligaments.

Flatter facet joints with a more horizontal orientation.

Incomplete ossification, making interpretation of bony alignment difficult (synchondrosis).

Uncinate processes do not calcify until approximately 7 years old.

Basilar odontoid synchondrosis fuses at 3 to 7 years old.

Apical odontoid epiphyses radiographically apparent at 7 years old but may not fuse until approximately 12 years old.

Posterior arch of C1 fuses at 4 years old.

Anterior C1 arch may not be visible until 1 year old and fuses at 7 to 10 years old.

Neural arches fuse to body by approximately 7 years old.

Posterior arches fuse by 3 to 5 years old.

Epiphyses of spinous process tips may mimic fractures.

Predental space 4 to 5 mm in those <8 years old and <3 mm in those ≥8 years old.

Pseudosubluxation of C2 on C3 seen in 40% of children 8 to 12 years old.

Prevertebral space size increases with phase of respiration.
The pediatric spine has greater elasticity of the supporting ligamentous structures than the adult spine. The joint capsules of the child have greater elastic properties, and the cartilaginous structures are less calcified than in adults. In the spine, there is a relatively horizontal orientation of the facet joints and uncinate processes, and the anterior surfaces of the vertebral bodies have a more wedge-shaped appearance. Compared with the adult, the child has relatively underdeveloped neck musculature and a disproportionately large and heavy head. These differences lead to an atonic fulcrum of the spine in children that is at the level of the C2 and C3 vertebrae versus the lower cervical vertebrae as found in adults. These combined anatomic features lead to higher cervical cord injuries and an increased incidence of cord injury without bone injury.33,34 Thus spinal cord injury without obvious radiographic abnormality (SCIWORA) is more common in children. SCIWORA may be a misnomer in the era of magnetic resonance imaging (MRI), because most injuries traditionally described as SCIWORA are seen immediately on MRI, albeit not plain radiographs. Treatment and prognosis are based upon neurologic presentation and MRI findings.33 Whenever a spinal injury is noted or suspected, careful attention should be paid to the entire spine as multilevel injuries are common.34

Clinical Features

Any patient with severe multiple injuries should be evaluated for spinal cord injury. Likewise, significant head, neck, or back trauma, trauma associated with high-speed MVCs or falls from a height onto the head should raise suspicions for spinal cord trauma. Likewise, significant head, neck, or back trauma, trauma associated with high-speed MVCs or falls from a height of more than 10 feet can lead to higher cervical cord injuries and an increased incidence of SCIWORA in children with apparently normal imaging. Patients with combined trauma, such as a fall from a height of more than 10 feet, or an MVC of any type and any combination of trauma, should be considered an indication of possible spinal cord injury. Many occipital cervical junction injuries are immediately fatal. However, survival is possible in some cases. Early detection and immobilization is crucial. Occipital cervical junction injuries should be suspected in any pediatric pedestrian versus vehicle collision. When obtained, plain radiographic evaluation should routinely consist of a cross-table lateral and an anteroposterior view. In children older than 8 years old, an open-mouth odontoid view should also be performed.36,37 The sensitivity of cervical spine plain radiographs is highly variable. Interpretation of plain cervical spine radiographs in children may be especially challenging because of the anatomic changes that occur with growth (see Box 165.10). In addition, pseudosubluxation of C2 on C3 is common on non-extended cervical spine radiographs in children up to adolescence, occurring in approximately 40% of patients. Pseudosubluxation and true subluxation on non-extended cervical spine radiographs can be distinguished through use of the posterior cervical line and the relationship of the spinolaminar line (also called the line of Swischuk) to the anterior cortical margin of the spinous process at C2 (Fig. 165.3). This line should maintain its integrity with no more than 1.5 mm of deviation. Exceptions to this guideline do occur, and the clinical scenario is taken into account before it is applied. Pseudosubluxation may be seen less commonly at C3 to C4.

An important criterion for radiographic clearing of the cervical spine is complete visualization of all seven cervical vertebral bodies on plain film down to and including the C7 to T1 interface. The predental space should be less than 5 mm in children younger than 6 years old, and the prevertebral soft tissue space should not be greater than normal (variable but generally one-third to one-half the vertebral body width through C4, and <14 mm at C6). The four cervical radiographic lines should be evaluated, and the atlanto-occipital alignment should be assessed for dislocation in this region. If there is any question of injury, thin-section CT and MRI can be used to delineate injury. If the dens cannot be adequately assessed by the open-mouth odontoid view, then a transforaminal view or CT scan should be used. Patients with high clinical suspicion for fracture but negative plain radiographs should be considered candidates for CT or MRI radiographic evaluation and specialist consultation.

The pretest likelihood of fracture is considered when decisions are being made regarding the removal of cervical immobilization in children with apparently normal imaging. Patients with continued neck pain despite negative radiographs or CT may require MRI evaluation.39 Rare cases may necessitate evaluation by neurosurgery under fluoroscopy. The use of flexion-extension views in the ED is rarely indicated nor helpful. If ligamentous injury is suspected, a MRI should be obtained; and if MRI is not available, consider CT in consultation with neurosurgery.

Young children are at greater risk for upper cervical spine injury. Many occipital cervical junction injuries are immediately fatal. However, survival is possible in some cases. Early detection and immobilization is crucial. Occipital cervical junction injuries should be suspected in any pediatric pedestrian versus vehicle collision. When obtained, plain radiographic evaluation should routinely consist of a cross-table lateral and an anteroposterior view. In children older than 8 years old, an open-mouth odontoid view should also be performed.36,37 The sensitivity of cervical spine plain radiographs is highly variable. Interpretation of plain cervical spine radiographs in children may be especially challenging because of the anatomic changes that occur with growth (see Box 165.10). In addition, pseudosubluxation of C2 on C3 is common on non-extended cervical spine radiographs in children up to adolescence, occurring in approximately 40% of patients. Pseudosubluxation and true subluxation on non-extended cervical spine radiographs can be distinguished through use of the posterior cervical line and the relationship of the spinolaminar line (also called the line of Swischuk) to the anterior cortical margin of the spinous process at C2 (Fig. 165.3). This line should maintain its integrity with no more than 1.5 mm of deviation. Exceptions to this guideline do occur, and the clinical scenario is taken into account before it is applied. Pseudosubluxation may be seen less commonly at C3 to C4.

An important criterion for radiographic clearing of the cervical spine is complete visualization of all seven cervical vertebral bodies on plain film down to and including the C7 to T1 interface. Pseudosubluxation and true subluxation on non-extended cervical spine radiographs can be distinguished through use of the posterior cervical line and the relationship of the spinolaminar line (also called the line of Swischuk) to the anterior cortical margin of the spinous process at C2 (Fig. 165.3). This line should maintain its integrity with no more than 1.5 mm of deviation. Exceptions to this guideline do occur, and the clinical scenario is taken into account before it is applied. Pseudosubluxation may be seen less commonly at C3 to C4.
accident, especially if the child has a laceration under the chin from a forward fall. In many fatal cases, distraction and displacement are obvious. However, in nonfatal cases, they can be subtle. A Power’s ratio greater than 1 indicates an atlanto-occipital dislocation until proven otherwise (normal, approximately 0.77). Power’s ratio is shown in Figure 165.4.

A traumatic or even sometimes nontraumatic atlantoaxial rotatory subluxation should be suspected in a child with a fixed rotatory cervical abnormality. Classically, this can be differentiated from a muscular torticollis in nontraumatic cases by the history, the time course, and the presence of palpable spasm of the sternocleidomastoid muscle on the side contralateral to the direction in which the chin is pointing in the case of torticollis. When atlantoaxial rotatory subluxation cannot be confidently ruled out clinically, plain radiographs or CT should be used.

In children with upper cervical spine tenderness, it is prudent to consider a fracture of the synchondrosis between the odontoid and C2. This can be difficult to diagnose on plain radiographs, but it is often recognized as a subtle anterior tilt to the odontoid on C2. A CT scan with sagittal reconstructions will clarify this entity.40

Management

There are two phases of spinal cord injury. Direct injury (initial phase) results in largely irreversible injury to the spinal cord. Indirect injury results from preventable or reversible injury to the spinal cord secondary to ischemia, hypoxemia, and tissue toxicity. Resuscitation of a patient with injury to the cervical spine should focus on prevention or minimization of the indirect causes of injury to the cervical spine. Management of possible spinal cord or column injury should begin in the out-of-hospital phase of emergency care. Most injured children arrive at the ED with adequate immobilization. For transport, the child who requires spinal motion restriction should be immobilized with a stiff cervical collar, a rigid backboard, and external fixation by means of head blocks, cloth tape, or straps to provide adequate precautions. Appropriate padding should be placed under the shoulder blades of the patient to approximate neutral alignment of the cervical spine and help prevent pressure-related injury. Some out-of-hospital protocols call for small children to be immobilized in their car seats. In the hospital, spinal immobilization should be maintained throughout the evaluation. However, even when thoracic or lumbar fractures exist, patients should be expeditiously removed from the backboard to prevent discomfort and morbidity. Sliding boards (smooth movers) can be used to move patients onto scanner tables and back to their trauma beds.

Breathing should be assessed to determine the presence of hypoventilation. Patients with spinal cord injury may hypoventilate because of diminished diaphragmatic activity or intercostal muscle paralysis. Supplemental oxygen should be given routinely, and ventilatory assistance by BMV or definitive airway management should be considered in the presence of clinically significant hypoventilation.

Circulatory status should also be addressed early to prevent end-organ perfusion deficits. Hypotension can result from hypovolemia, neurogenic shock, spinal shock, or other less common causes. Spinal shock usually results from injury above the level of T1. It manifests with lower extremity findings of spinal cord injury, with flaccid paralysis of skeletal and smooth muscle leading to the appearance of a relative hypovolemia caused by diminished systemic vascular resistance. Spinal shock generally resolves in hours to approximately 1 day once some spinal level reflexes return below the site of injury. Neurogenic shock typically occurs after injury to the spinal cord above the level of approximately T6. Patients with neurogenic shock lose their
sympathetic tone and demonstrate hypotension in the face of unopposed parasympathetic action, such as bradycardia. In each case, fluid administration, parasympathetic receptor blocking agents (such as, atropine or glycopyrrolate) and vasopressors with chronotropic, vasoactive, and inotropic characteristics (eg, dopamine) are used. If spinal shock with normal chronotropy and inotropy is found, then fluids and agents with more peripheral vascular vasoconstrictive properties may be preferable, such as phenylephrine or norepinephrine. Spinal and neurogenic shock remain diagnoses of exclusion once hemorrhagic shock has been definitively eliminated.

Immediate evaluation by a spinal cord specialist should be sought for all children with spinal cord injury. In the absence of such a specialist, the patient should be transported to a center with adequate facilities to care for spinal cord–injured patients.

**Cardiothoracic Injury**

**Principles**

Most serious chest injuries in children are caused by blunt trauma and result from MVCs, pedestrian accidents, and falls. Isolated chest injury is a relatively infrequent occurrence considering the typical mechanisms of blunt trauma in the pediatric patient. Pediatric trauma patients with thoracic injury have a twentyfold increase in mortality over pediatric trauma patients without thoracic trauma. Sequelae of blunt injury include pulmonary contusion, pneumothorax, hemothorax, myocardial injury, pericardial injury, vascular injury, and rib fractures.

Children subjected to penetrating trauma, in contrast to the injuries associated with blunt trauma, often die from the primary insult. Nationwide misuse of firearms has resulted in an increasing incidence of penetrating trauma, often with children as victims. Specific clinical patterns should alert the emergency clinician to the potential for concurrent abdominal and thoracic injury. Any patient with penetrating trauma at or below the level of the nipples falls into this category. Apparent isolated thoracic trauma does not exclude abdominal injury.

It is important to understand the physiology of pediatric respiration in considering the potential for early decompensation after chest injury; any impairment of diaphragmatic mobility compromises ventilation. The presence of gastric distention elevates the diaphragm and severely diminishes the vital capacity of a child. In addition, the particular types of muscle fibers involved in the diaphragm of infants and young children predispose them to the sudden development of apnea when these muscles become fatigued. Unlike adults, whose thoracic wall musculature can pull the ribs up anteriorly to give a larger circumference to the chest wall, children’s chest wall circumference does not change drastically during respiration, because a child’s chest is barrel-like throughout the respiratory cycle. This also decreases the ability of children to increase their vital capacity. For these reasons, children will increase ventilation typically by increasing their respiratory rate. Most important, the presence of adequate oxygenation in a pediatric patient does not always ensure sufficiency of ventilation, necessitating confirmatory auscultation. End-tidal carbon dioxide capnography can be very useful in this regard in both the intubated and the nonintubated trauma patient.

Infants and children are anatomically protected against blunt thoracic cage trauma because of the compliance of the rib cage. Compressibility of the rib cage dissipates the force of impact, which lessens the likelihood of bony injury. However, this protective mechanism may mask complex pediatric thoracic insults. The compliance of the rib cage allows significant injury to occur with little apparent external signs of trauma. Multiple rib fractures are a marker of serious injury in children. In addition, the pediatric mediastinum is mobile, which favors the development of rapid ventilatory and circulatory collapse in the presence of a tension pneumothorax.

**Specific Disorders**

**Pneumothorax.** The development of a traumatic pneumothorax is commonly associated with significant pulmonary injury. In contrast to spontaneous pneumothoraces, these insults do not resolve spontaneously and often are associated with the presence of a hemothorax. Signs and symptoms include external evidence of chest trauma, such as abrasion, contusion, or ecchymoses; tachypnea; respiratory distress; hypoxemia; and chest pain. Decreased breath sounds may not be appreciated in children with pneumothoraces because of the wide transmission of breath sounds in the chest and upper abdomen. Emergency clinicians should listen to the chest from the axilla in children; this location helps with lateralization to distinguish decreased breath sounds on one side compared with the other. Extended FAST procedure performed by the emergency clinician during the initial trauma evaluation, utilizing B mode and M mode ultrasound, have high sensitivity and accuracy for diagnosing pneumothorax. Plain radiography should be performed, however ultrasound of the chest has high sensitivity in detecting pneumothorax in a child and should be performed when a pneumothorax is suspected but not present on plain radiography.

Management of a hemothorax includes the placement of a large-caliber chest tube (largest tube that can fit between the ribs; or estimated as four times the endotracheal tube size) far enough posteriorly, near the mid-axillary line, to prevent encroaching on more anterior soft tissue that will later become part of the breast. Chest tube size for hemothorax management can be found in Box 165.2 or on a length-based resuscitation tape. A chest tube should be considered for any patient with a pneumothorax who will be undergoing mechanical ventilation. Some small (<20%) simple pneumothoraces without tension may be managed with observation and 100% oxygen supplementation in a child not being mechanically ventilated. Reassessments can be accomplished by repeat chest radiographs at selected intervals, or a pigtail catheter can be placed percutaneously.

**Open Pneumothorax.** An open pneumothorax exists when the chest wall is injured sufficiently to allow bidirectional flow of air through the wound. The patient is unable to expand the lung because of equalization of pressures between the atmosphere and the chest cavity. Ventilation and oxygenation are severely impaired.

Management of an open pneumothorax is dictated by the size of the defect and the amount of respiratory compromise. A simple, small, open pneumothorax in a breathing patient may be treated by covering the chest wall defect with occlusive dressing, such as sterile petroleum gauze, and performing a separate incision for a thoracostomy tube. Defects that are too large to seal adequately and patients with ventilatory failure are candidates for intubation.

In the out-of-hospital setting, a bandage applied over an open pneumothorax wound and taped on three sides as a temporizing measure may allow air to escape during expiration but not to enter during inspiration.

**Tension Pneumothorax.** Pulmonary air leaks that occur in a one-way valve arrangement favor the development of a tension pneumothorax. Increasing amounts of free air within the pleural cavity cause the mediastinal structures to shift toward the opposite side, compromising cardiac output. The final common pathway involves hypoxia, hypotension, and refractory shock. Most patients with tension pneumothoraces have severe respira-
Diaphragmatic Contusion. Vascular Injuries. Children involved in blunt trauma with CPR for longer than 10 minutes with asystole and no signs of life on presentation without ultrasound evidence of cardiac tamponade and (2) penetrating trauma with CPR for greater than 15 minutes and asystole with no signs of life on arrival without ultrasound evidence of cardiac tamponade.45

Pulmonary Contusion. Penetrating and blunt thoracic trauma may result in the development of a pulmonary contusion. The compliance of the rib cage in children renders them susceptible to the development of pulmonary contusion even in the absence of external signs of chest trauma. Injury to capillary membranes allows blood to collect within the interstitial spaces, resulting in hypoxia and respiratory distress. If bleeding is severe enough, oxygenation and ventilation are impaired. Initial chest radiographs may not show the classic findings of pulmonary consolidation. In addition, in the early stages of injury, blood gases may be normal.

Treatment of pulmonary contusions includes a careful evaluation for the presence of additional injuries because significant force is necessary to cause the contusions. Most patients may be treated with supplemental oxygen and close monitoring. Most pulmonary contusions resolve without sequelae. Rare cases are associated with the development of acute respiratory distress syndrome.

Traumatic Diaphragmatic Hernia. Children involved in MVCs who are wearing lap belts are predisposed to the development of diaphragmatic herniation. Mechanisms of injury involve sudden increases in intra-abdominal pressure. Patients initially are in stable condition, with the degree of respiratory distress directly proportional to the amount of abdominal contents that protrude into the pulmonary space. The presence of bruisng from lap belt–only compression should alert the clinician to the possibility of diaphragmatic hernia and other intra-abdominal injuries (small bowel injury) and the possibility of associated thoracolumbar spinal insults, such as Chance fractures. Most commonly, the herniation occurs on the left side because the liver prevents herniation of bowel on the right.

Initial management for these patients involves placement of a nasogastric tube to decompress the stomach. In cases of severe respiratory distress, intubation is indicated. BMV is avoided whenever possible. Surgery is required for repair of the injury.

Cardiac and Vascular Injuries. Injuries to the heart and large vessels are uncommon in children and rarely happen in isolation. In cardiac and vascular injuries, an electrocardiogram may show tachycardia with low voltage (pericardial tamponade), findings consistent with acute myocardial ischemia, or a variety of other nonspecific abnormalities. Patients with dysrhythmias, ST-segment abnormalities, and hypotension (without another cause) should be admitted with a pediatric cardiologist consulted and undergo further testing (eg, echocardiogram).

The most common traumatic cardiovascular injury sustained by children is myocardial contusion. Patients often have chest wall tenderness or may report generalized chest pain. Tachycardia is the most common finding. Echocardiogram may be diagnostic. Patients with myocardial contusions should be monitored closely for the development of dysrhythmias and impaired myocardial function; however, in most cases of myocardial contusion, there are no long-term sequelae.

The most life-threatening scenario involving the cardiac structures is the development of cardiac tamponade. Penetrating wounds with myocardial penetration and tamponade are potentially survivable if recognized immediately. Extravasated blood fills the pericardial space and impairs cardiac filling during diastole. Clinically, patients demonstrate tachycardia, distant heart sounds, narrow pulse pressure, jugular venous distention, and
Comotio cordis is a disorder described in pediatric patients that results from sudden impact to the anterior chest wall (e.g., when a child is struck in the chest with a thrown or hit baseball), which causes cessation of normal cardiac function. The patient may have an immediate dysrhythmia or ventricular fibrillation that is refractory to resuscitation efforts. Significant morbidity and mortality are associated with this disorder, and although most patients recover completely, some require extended treatment with antiarrhythmic agents. The combination of these factors provides the basis for the differences in abdominal injury patterns seen between children and adults.

Comotio Cordis. Comotio cordis is a disorder described in pediatric patients that results from sudden impact to the anterior chest wall (e.g., when a child is struck in the chest with a thrown or hit baseball), which causes cessation of normal cardiac function. The patient may have an immediate dysrhythmia or ventricular fibrillation that is refractory to resuscitation efforts. Significant morbidity and mortality are associated with this disorder, and although most patients recover completely, some require extended treatment with antiarrhythmic agents, cardiac pacemaker placement, inotropic agents, or an intra-aortic balloon pump. In patients with prolonged cardiac instability, this disorder, and although most patients recover completely, efforts. Significant morbidity and mortality are associated with this disorder, and although most patients recover completely, some require extended treatment with antiarrhythmic agents, cardiac pacemaker placement, inotropic agents, or an intra-aortic balloon pump. In patients with prolonged cardiac instability, cardiogenic shock and death may occur despite maximal therapeutic intervention.

**Abdominal Injury**

**Principles**

Abdominal trauma is the third leading cause of traumatic death in children after head and thoracic injuries. Blunt trauma related to MVCs causes more than half of abdominal injuries in children and is the most lethal. “Lap belt” injury, including small bowel injury and Chance fractures, may occur in restrained children involved in MVCs. Another common cause of abdominal injury involves handlebar injuries from bicycle crashes. Often, the effects of bicycle injuries may not be seen on initial presentation, with the mean elapsed time to onset of symptoms being nearly 24 hours after injury. All children with epigastric pain after blunt trauma, especially when concentrated force has been applied in this area, should be considered to have a duodenal hematoma or pancreatic injury.

Sports-related injuries are another common cause of pediatric abdominal trauma. Sports-related injuries are associated most commonly with isolated organ injury as a result of a blow to the abdomen. At particular risk are the spleen, kidney, and intestinal tract. Finally, abdominal injury is second only to head injury as a cause of death in child abuse cases. All abuse victims should be screened carefully for abdominal trauma (see Chapter 177).

The anatomy of the child lends special protection from some abdominal injury patterns and predisposes the child to other types of injuries. Children have proportionally larger solid organs, less subcutaneous fat, and less protective abdominal musculature than adults. Therefore they have relatively more solid-organ injury. Children have relatively larger kidneys with fetal lobulations that predispose them to renal injury. Children also have a fairly flexible cartilaginous rib cage that allows for significant excursion of the lower chest wall, permitting compression of the internal organs. The combination of these factors provides the basis for the differences in abdominal injury patterns seen between children and adults.

**Clinical Features**

Pediatric patients with multiple injuries often have blunt abdominal injury. In children, history is often limited, traditional signs of compensation are often not as evident, and physical examination can be difficult.

Signs and symptoms of abdominal injury in children include tachypnea from impaired diaphragmatic excursion, abdominal tenderness, ecchymoses, and signs of shock. Restrained children involved in MVCs with abdominal bruising are much more likely to have an intra-abdominal injury than those without bruising. Abdominal distention is a common nonspecific finding that is often the result of air swallowing subsequent to a painful event.

Children with hepatic and splenic injuries may have trouble localizing their pain. Kehr’s sign (left shoulder pain with spleen injury) may be the only indication of an intra-abdominal injury. Any abdominal tenderness on examination should prompt further evaluation of the abdomen. Vomiting can be associated with duodenal hematoma or traumatic pancreatic injury but is usually a late sign. Signs of small bowel injury may be delayed and noted clinically only with serial examinations.

Pelvic bone stability should be assessed in cases of abdominal trauma, and a genital examination searching for signs of injury should be performed. Rectal examination is insensitive and nonspecific when used as a general screening test for all patients after serious trauma. Rectal examination should only be performed in patients with concern for specific injuries such as for rectal tone when there is concern for spinal injury, or to evaluate for blood in the case of penetrating colon injury.

Even minor falls can result in significant splenic injury. Repeated examination, prolonged observation, and close attention to vital signs are warranted for children who have sustained a direct blow to the abdomen. Any child with clinically suspicious abdominal examination findings or significant direct trauma should be evaluated further with additional radiologic and laboratory studies or admission for serial examinations.

**Diagnostic Testing and Management**

In patients with suspected abdominal injury, management and resuscitation must be rapid. In children who have undergone major trauma and have no evidence of urethral trauma, a urinary catheter should be considered for bladder decompression, evaluation for the presence of urinary retention, examination for the presence of blood in the urine, and monitoring of urine output. Urinary catheter size estimates are shown in Box 165.2.

A careful examination and diagnostic laboratory testing can be useful in identifying children at lower risk for intra-abdominal injury. Intra-abdominal injury is unlikely in the absence of the following: hypotension (age-adjusted), abdominal tenderness, a femur fracture, increased liver enzyme levels (serum aspartate aminotransferase concentration >200 U/L or serum alanine aminotransferase concentration >125 U/L), microscopic hematuria (urinalysis >5 RBCs/high powered field), or an initial hematocrit level less than 30. Liver enzyme testing is particularly useful to risk stratify patients with equivocal examination findings. Victims of suspected child abuse should also undergo liver enzyme testing and those with transaminase levels more than 80 U/L should undergo CT of abdomen and pelvis to assess for abdominal injury.

The diagnostic test of choice to assess intra-abdominal injury in stable patients at high risk for injury is abdominal CT. The FAST examination can be a useful adjunct. The finding of intraperitoneal hemorrhage alone on ultrasound is not necessarily an indication for surgery in a stable pediatric patient; but when the FAST is positive, it will clarify the need for abdominal CT, close observation, and possible repeat ultrasound examinations.
In hemodynamically unstable children, FAST may point to the abdomen as the source of hemorrhage and may expedite the decision to operate.

Indications for laparotomy are listed in Box 165.11. Patients who remain hypotensive after adequate crystalloid infusion, have active arterial bleeding on CT scan, or have consistent decreases in their hemoglobin level are likely candidates for early invasive intervention. Exploratory laparoscopy or laparotomy is often required for these critically injured patients, but patients with a known source of bleeding may be appropriate candidates for arterial embolization in an angiography suite.56

Spleen Injury. Injuries to the spleen are the most common injuries in pediatric abdominal trauma. Children with injuries from MVCs, sudden deceleration injuries, and contact sports–related injuries may sustain splenic trauma. Typical findings include left upper quadrant abdominal pain radiating to the left shoulder. The abdominal examination may show evidence of peritoneal irritation in the left upper quadrant of the abdomen. Patients may be hemodynamically stable or, after significant splenic rupture or laceration, may be persistently hypotensive or in fulminant cardiovascular collapse. Stable patients may undergo CT for radiologic evaluation.

Most often with minor splenic trauma, bleeding is controlled spontaneously without operative intervention; however, all patients with a splenic injury should be evaluated by a surgeon. In patients with a contained, splenic subcapsular hematoma, extracapsular bleeding may occur days after capsular rupture. Patients with splenic injury should be admitted to the hospital for close observation and repeated examinations. Because of the desire for splenic salvage to maintain immunocompetency, an injured spleen is often left in place as long as the patient can be resuscitated adequately with crystalloid and blood products.

Liver Injury. The liver is the second most commonly injured solid organ in the pediatric patient with abdominal trauma; however, it is the most common cause of lethal hemorrhage. Tenderness on palpation of the right upper quadrant of the abdomen, the complaint of abdominal pain in this region, and pain in the right shoulder are signs of possible liver injury. Patients managed conservatively with crystalloid and/or blood transfusion often do well. Once liver injury is detected on CT scan, close observation in the hospital, serial abdominal examinations, and serial hemoglobin measurements are recommended.

Renal Injury. The kidney is more susceptible to injury in children than in the adults due to the potential for remnant fetal lobules, increased organ mobility with rapid deceleration mecha-

**BOX 165.11**

**Indications for Laparotomy**

- Hemodynamic instability despite aggressive resuscitation and appropriate ED procedures (eg, a decompression hemothorax or tension pneumothorax)
- Hemodynamic instability despite resuscitative efforts and evidence of intraperitoneal free fluid on bedside ultrasound examination (FAST)
- Transfusion of ≥50% of total blood volume because of massive intraperitoneal bleeding
- Radiographic evidence of pneumoperitoneum, intraperitoneal bladder rupture, grade V renovascular injury
- Gunshot wound to the abdomen
- Evisceration of intraperitoneal or stomach contents
- Signs of peritonitis

ED, Emergency department; FAST, focused assessment with sonography in trauma.

DISPOSITION

The primary role of the emergency clinician is to evaluate and stabilize the patient before admission or transfer to a facility with a higher level of care available. Infants and younger children who are moderately to severely injured have improved outcomes in pediatric specific ICUs.61

Before any transport, the patient should be maximally stabilized. This may include the involvement of general surgeons, definitive surgery, or temporizing surgery (such as, packing the abdomen). The emergency clinician should communicate directly with the accepting physician at the tertiary care center. In general, the emergency clinician should refrain from completing extensive radiologic testing in a facility that is potentially unable to manage nisms, and lack of protective intraabdominal musculature; there is also a tendency for congenital renal abnormalities, which are susceptible to injury (eg, the horseshoe kidney) to be discovered at a young age after trauma. For these reasons, even though the kidney is less susceptible to trauma from forces applied to the anterior abdomen, it is often injured in the pediatric patient with multiple injuries.56,57 Because this organ is retroperitoneal, signs and symptoms of kidney injury are often less obvious and more diffuse than signs and symptoms of other abdominal organ injuries. Often, dull back pain, ecchymosis in the costovertebral region, and hematuria are the only clues to renal injury. CT and renal ultrasound may be used in a stable patient to assess the degree of renal involvement. For most patients, initial CT scan of the abdomen to assess for genitourinary injury is indicated when there is gross hematuria, microscopic hematuria and shock, and penetrating injury to the abdomen with or without hematuria. Major deceleration injuries also pose a risk of genitourinary injury and low threshold for imaging in these cases even with microscopic hematuria should be exercised.

Other organs, such as the pancreas and gastrointestinal tract, are less frequently injured in pediatric patients but may have delayed presentations.

Penetrating Injury. Penetrating wounds to the abdomen usually require rapid evaluation by a surgeon and consideration of operative intervention. With hemodynamic instability, or peritonitis, urgent laparotomy is indicated. In the hemodynamically stable patient, further evaluation with a CT scan, local wound exploration, diagnostic laparoscopy, and observation may be warranted. Diagnostic peritoneal tap (DPT) and diagnostic peritoneal lavage (DPL) have been largely supplanted by other diagnostic modalities in modern practice, such as CT and diagnostic laparoscopy.59 Children with a positive DPL should receive fluid and or transfusion in the ED, and children with a positive DPL do not necessarily require surgical intervention because of splenic salvage.

Radiology. Pediatric patients frequently sustain injury to the spleen, liver, kidneys, and gastrointestinal tract. CT of the abdomen with IV contrast can provide high sensitivity and specificity for identification of these injuries while being relatively noninvasive.56 Abdominal CT has a high negative predictive value.56 Oral contrast should not be used; it does not add to the accuracy of CT for trauma and can lead to a delay in evaluation, and risk of aspiration.

Although radiologic evaluation can provide important diagnostic information in a pediatric patient with possible abdominal trauma, any patient with unstable vital signs from an obvious surgically correctable cause should receive immediate operative intervention and not be subjected to delay while radiographic screening studies are obtained. Children with persistent or recurrent hypotension, continued abdominal pain, or persistent abdominal distention should undergo evaluation by a surgeon.
Indications for admission include operative intervention and need for ongoing monitoring. The threshold for admission should be low in cases in which the health care team does not believe the child will have the social support or oversight necessary to be appropriately observed or to recover at home.

**KEY CONCEPTS**

- Trauma is the leading cause of death in children in the United States.
- Avoid hypoxia and hypotension by early administration of oxygen and assisted ventilation, and fluid resuscitation with crystalloid at 20 mL/kg increments. Initiate transfusion of 10 mL/kg of PRBCs if hypotensive or remains with signs of hypovolemic shock after 40 mL of crystalloid is infused.
- Key pediatric anatomic and physiologic differences include:
  - Children are smaller, so force is more widely distributed through the body of a child, making multi-system injuries more likely.
  - The infant’s head-to-body ratio is greater, creating a relatively higher center of gravity. This combined with a less myelinated brain and thinner cranial bones may result in more serious head injury.
  - Children have a higher anatomic fulcrum in the cervical spine (C2 to C3 in children <8 years old). This leads to higher C-spine injuries.
  - Children have more lax ligaments of the cervical column. This leads to an increased risk of SCIWORA.
  - Children have more horizontally positioned ribs meaning that with inspiration, the ribs move only up and not out. This leads to a limited ability to increase tidal volume and risk for respiratory failure with chest or diaphragmatic injury.
  - Children have more elastic chest walls that allow for pulmonary injury without skeletal injury.
  - Children have thinner abdominal walls and have more anterior livers and spleens. This results in a greater chance of injury to those organs.
  - Children have excellent compensatory mechanisms. They can remain normotensive until they lose large amounts of intravascular volume. Hypotension is a very late sign.
  - Continuous monitoring and reassessment of the trauma patient is essential to recognize early signs of deterioration and to discover all injuries.
  - Most minor head trauma may be managed with observation and without CT imaging. Clinical decisions rules when applied may reduce imaging and exposure of children to ionizing radiation.
  - In major trauma patients indications for intubation include respiratory failure or a GCS less than 9.
  - Most cases of shock in trauma are due to hypovolemia so fluid resuscitation with normal sale is recommended, and the addition of packed cell transfusions should be initiated in a pediatric trauma patient with hypotension or with signs of shock after 40 to 60 mL/kg normal saline.
  - The diagnostic test of choice for the evaluation of intra-abdominal injury in a stable patient with high suspicion for injury is CT of the abdomen.
  - Splenic injuries are generally treated conservatively in children to ensure immunocompetence.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

165.1. A 5-year-old male is struck by a car while riding a bicycle. On presentation, he exhibits hypotension, a normal heart rate, and quadriplegia. You suspect neurogenic hypotension secondary to spinal shock and attempt to correct the hypotension with fluids but are not successful. Which of the following should be your first choice for a vasopressor?
A. Dobutamine
B. Dopamine
C. Epinephrine
D. Phenylephrine

Answer: D. Spinal shock is related to decreased systemic vascular resistance (SVR). A pressor with primarily alpha vasoconstrictive effects, such as phenylephrine or norepinephrine, is the best choice for increasing SVR without having other physiologic effects.

165.2. A 6-week-old infant is brought to your emergency department (ED) by his mother after he reportedly fell 3 feet from his changing table approximately 45 minutes ago. His mother reports that the child did not lose consciousness and “seems fine.” She is concerned, however, by a large scalp hematoma that developed almost immediately. What is your most important intervention at this point?
A. Consulting a social worker to help screen for child abuse
B. Head computed tomography (CT) scan
C. Ice packs for the scalp hematoma
D. Observation in the ED for 4 hours
E. Skull radiographs

Answer: B. A 6-week-old infant is at high risk for intracranial injury given the softness/deformability of the skull. Scalp hematomas signify possible skull fracture and thus CT of the head is indicated.

165.3. Which of the following is the most commonly injured solid organ in pediatric patients with abdominal trauma?
A. Bladder
B. Duodenum
C. Kidney
D. Liver
E. Spleen

Answer: E. Injuries to the spleen are the most common injuries in pediatric abdominal trauma. Children involved in motor vehicle collisions (MVCs), sudden deceleration injuries, and contact sports–related injuries may sustain splenic trauma. Treatment includes fluid resuscitation and blood transfusion as needed. Splenic salvage is important for immunocompetence in children and operative intervention is avoided as long as the patient can be stabilized with fluid resuscitation.

165.4. A 4-year-old female is brought to your emergency department (ED) from the scene of an motor vehicle collision (MVC). Paramedics intubated the child in the field because she was unresponsive at the scene. On arrival, her vital signs are within normal limits. Before transport to the computed tomography (CT) scanner, however, you note that she is becoming mildly bradycardic and hypertensive. Her left pupil becomes dilated and nonreactive. Which of the following should be your next immediate action?
A. Hyperventilation to a carbon dioxide (CO₂) level between 30 and 35 mm Hg
B. Mannitol administration
C. Nicardipine infusion
D. Phenytoin administration
E. Proceed immediately to the CT scanner

Answer: A. The patient’s sudden onset of dilated, nonreactive pupil, along with bradycardia and hypertension, is indicative of acute brain herniation. Immediate hyperventilation to a goal of CO₂ between 30 and 35 mm Hg has been shown to reduce brain injury. CT scanning should not be performed before this potentially lifesaving intervention. The administration of a hypotensive agent, such as mannitol or hypertonic saline, is indicated but should not take precedence over hyperventilation. Phenytoin is arguably indicated in this patient but not necessary in the acute setting. Nicardipine and other antihypertensive agents have no place in the management of a head-injured child. Her hypertension is a physiologic response to brain herniation, in which increasing mean arterial pressure (MAP) preserves cerebral perfusion pressure (CPP).

165.5. A 7-year-old girl is brought into the emergency department (ED) by emergency medical service (EMS) personnel from the scene of an motor vehicle collision (MVC). On your primary survey, she is noted to have a clear airway, decreased breath sounds in the right lung field, subcutaneous emphysema, and tracheal deviation to the left. She has thready distal pulses. What is your next step in stabilizing this patient?
A. Airway control with endotracheal intubation (ETI)
B. Bag-mask ventilation (BMV)
C. Immediate needle thoracostomy in the second midclavicular space on the right
D. Portable chest radiograph to confirm diagnosis

Answer: C. This patient is presenting with signs of tension pneumothorax. In this case, immediate decompression with a needle thoracostomy, followed by the placement of an appropriately sized chest tube or immediate chest tube placement is required to avoid cardiovascular collapse.

165.6. Which of the following statements regarding chest injuries in children is correct?
A. Aortic transection is more likely in a pediatric patient than in an adult patient.
B. Multiple rib fractures without significant underlying lung injury are common in children.
C. Penetrating chest trauma is more common than blunt chest trauma in pediatric patients.
D. Significant pulmonary contusions may be present in the absence of rib fractures in children.

Answer: D. The pediatric rib cage has more compliance than an adult rib cage. This makes children predisposed to pulmonary injury in the absence of bony injury. Rib fractures are more rare in the pediatric population because of this, and their presence is concerning for underlying lung injury. Blunt chest trauma is more common than penetrating chest trauma in pediatric patients and concurrent chest and abdominal injuries are common. Aortic transection is more common in adults.

165.7. A 12-year-old male fell while climbing over a 12-foot barbed-wire fence and sustained a deep 10-cm laceration to his medial left thigh. There is active bleeding from the laceration. What is the first step in the management of this patient?
A. Apply a tourniquet to the leg.
B. Begin with a primary survey and assess the patient’s airway and breathing.

Answer: B. The patient’s sudden onset of dilated, nonreactive pupil, along with bradycardia and hypertension, is indicative of acute brain herniation. Immediate hyperventilation to a goal of CO₂ between 30 and 35 mm Hg has been shown to reduce brain injury. CT scanning should not be performed before this potentially lifesaving intervention. The administration of a hypotensive agent, such as mannitol or hypertonic saline, is indicated but should not take precedence over hyperventilation. Phenytoin is arguably indicated in this patient but not necessary in the acute setting. Nicardipine and other antihypertensive agents have no place in the management of a head-injured child. Her hypertension is a physiologic response to brain herniation, in which increasing mean arterial pressure (MAP) preserves cerebral perfusion pressure (CPP).
C. Obtain intravenous (IV) access and begin blood transfusion immediately.
D. Pack the wound to decrease hemorrhage.

Answer: B. The primary survey should quickly assess the airway, breathing, and circulation (ABCs). Initial wound management involves the application of direct pressure to the wound. Approaching trauma patients in a systemic fashion will ensure that large, obvious injuries do not distract from the detection of other injuries. Oftentimes multiple interventions would be done simultaneously. Jaw thrust to open an airway and then another health care providers quickly applying hemorrhage control. The child in the question also fell from a fence and may have other fall-related injuries.

165.8. Which of the following statements regarding imaging of a multi-trauma pediatric patient is correct?
A. A negative computed tomography (CT) scan of the cervical spine rules out spinal cord injury, and if normal, immobilization can be discontinued.
B. A negative focused assessment with sonography in trauma (FAST) examination rules out traumatic intra-abdominal injury, making a CT scan unnecessary.
C. In a hemodynamically stable pediatric trauma patient, CT imaging should be complete before transfer to a pediatric trauma facility, even if it delays transfer.
D. In a hemodynamically stable pediatric patient with a high level of concern for intra-abdominal trauma, CT scan is the imaging test of choice.

Answer: D. CT scan is the diagnostic test of choice for evaluation of intra-abdominal trauma in children. Spinal cord injury without radiologic abnormality (SCIWORA) is more common in pediatric patients, and normal cervical spine CT scan does not rule out spinal trauma. Although often a useful adjunct, a FAST examination does not rule out intra-abdominal injury. In a hemodynamically stable patient, CT imaging does not need to be complete before transfer to a pediatric trauma center and should not delay transfer. With clinical concern for elevated intracranial pressure (ICP), treatment (eg, hyperventilation, mannitol, or hypertonic saline) should be initiated immediately.
CHAPTER 166

Pediatric Fever

Nathan W. Mick

PRINCIPLES

Background

Fever is the most common chief complaint of pediatric patients presenting to the emergency department (ED). Most cases of fever are viral in origin, benign in course, and resolve spontaneously. Management of children with fever varies by the age of the child, with the following common divisions: 0 to 28 days old, 1 to 2 months old, 2 to 3 months old, 3 to 6 months old, 6 to 36 months old, and 3 years old to adulthood. These divisions reflect differing immunologic and vaccination milestones as well as a spectrum of age-specific pathogens.

Anatomy and Physiology

Fever is defined as any elevation in body temperature equal to or above 100.4°F (38.0°C). The most reliable method to measure temperature is with a rectal thermometer and is the preferred method of measurement in high-risk groups, such as infants 0 to 3 months old. However, the rectal route should not be used in patients who are potentially immunocompromised (eg, children with fever who are receiving cytotoxic chemotherapy) because of the risk of mucosal damage leading to bacteremia. The cutoff for a clinically significant fever (ie, one that may trigger a laboratory evaluation) varies with the age and immunologic status of the child. A rectal temperature of 100.4°F (38.0°C) is considered to be a clinically significant fever in an infant younger than 3 months, whereas a toddler with a temperature of 103.1°F (39.5°C) and an upper respiratory infection may not need any evaluation beyond a thorough history and physical examination.

Pathophysiology

Causes of fever vary with the age of the child (Table 166.1). The majority of pediatric fever is due to infections, and most infections are attributable to a viral source. Upper respiratory infections, viral gastroenteritis, croup, bronchiolitis, stomatitis, roseola, infectious mononucleosis, and varicella are all known causes of fever. Most viral illnesses are benign and self-limited, but infection with measles, herpes simplex virus (HSV), or respiratory syncytial virus (RSV), can lead to significant morbidity and mortality, particularly in the first month of life.

Bacterial disease is also an important cause of fever in children. Serious bacterial illness (SBI) is typically defined as the presence of pathogenic bacteria in a previously sterile site and includes urinary tract infection (UTI), bacteremia, meningitis, osteomyelitis, bacterial gastroenteritis, bacterial pneumonia, cellulitis, and septic arthritis. The risk of SBI in febrile infants younger than 3 months old with a temperature of 100.4°F (38.0°C) or greater to be between 6% and 10%; children younger than 28 days old have the highest incidence. Pathogens change during early infancy, with vertical transmission of organisms such as group B streptococcus, Listeria monocytogenes, and HSV being more common in neonates. By 1 to 2 months old, organisms such as Streptococcus pneumoniae, Neisseria meningitidis, and urinary pathogens (Escherichia coli or Enterococcus) become more common. In all children younger than 3 months old, the urinary tract is the most common site of infection, followed by bacteremia and meningitis. UTIs are more common in white girls compared with other races and are of higher prevalence in patients in whom no source for infection is found and who have higher temperatures (ie, >102.2°F [39.0°C]).

Children younger than 3 months old may present with an apparent viral syndrome and still harbor SBI. Levine and colleagues studied 1248 infants younger than 60 days old who had temperatures above 100.4°F (38.0°C). Of these children, 22% were positive for RSV. Although, overall, children with documented RSV had a lower incidence of concomitant SBI than did those without RSV (12.5% vs. 7%), there was no significant difference in rates of SBI in children younger than 28 days old (14.2% in RSV-negative neonates vs. 10.1% in RSV-positive infants). Most of the bacterial infections were UTIs. Older children 3 to 36 months old with recognizable viral syndromes (eg, croup, bronchiolitis, varicella, stomatitis) have a very low incidence of bacteremia. In over 1300 patients with temperature above 102.2°F (39.0°C) who had a recognizable viral syndrome, the risk of bacteremia was 0.2%.

Occult bacteremia describes the presence of pathogenic bacteria in the bloodstream of a well-appearing febrile child in the absence of a focus of infection; it was first described as a clinical entity in the 1970s. The term typically refers to children 3 to 36 months old who are highly febrile (>102.2°F [39.0°C]) but appear well. Before the adoption of the conjugate vaccines against Haemophilus influenzae type b and S. pneumoniae, the incidence of bacteremia in this population was approximately 5%. Vaccination has proved remarkably effective, nearly eradicate H. influenzae type b as a significant pathogen and greatly reducing the burden of pneumococcal disease (Fig. 166.1). Currently, the rate of occult bacteremia is less than 1%, with pathogens such as N. meningitidis becoming proportionally more prevalent. Urinary pathogens, occurring in 5% of febrile children younger than 2 years old, continue to be an important source of bacterial illness in infants and children. Risk factors include female sex, absence of another apparent source of infection, fever higher than 102.2°F (39.0°C), white race, and for boys, uncircumcised status.

Bacterial illness in school-age children and adolescents includes focal infections, such as streptococcal pharyngitis, cellulitis, and pneumonia, as well as bacteremia and meningitis. N. meningitidis has a bimodal distribution, with the highest incidence in children younger than 12 months old (9.2/100,000 population). A second peak occurs during adolescence, when the rate of illness is 1.2/100,000 population, with a significant proportion of cases occurring in college students who reside in a dormitory setting (3.2/100,000 population).

Although it is much less common than in viral or bacterial infection, fever can also be a presenting sign of autoimmune diseases, such as juvenile rheumatoid arthritis or Kawasaki disease. Central nervous system (CNS) lesions such as brain tumors also can infrequently be manifested with fever.
The body’s ability to fight infection varies with age. Maternal antibodies confer some protection after birth, but the infant’s immune system is initially inadequate, particularly T-cell function and the ability to mount an immunoglobulin G response to infection. The immature neonatal immune system as well as exposure to certain pathogens during the birthing process (eg, group B streptococcus, Chlamydia trachomatis, Neisseria gonorrhoeae) places the newborn at particular risk for SBI. Young infants are also at risk for disseminated infection, because they are unable to mount the immune response needed to prevent a localized infection from spreading. Thus a simple cellulitis, mastitis, omphalitis, or, rarely, gonococcal eye disease, can lead to sepsis or focal seeding of the CNS. Immune function improves during the first 2 to 3 months of life as does the ability to assess a child clinically. Infants begin the primary series of vaccinations against acquired infections, such as *S. pneumoniae* and *H. influenzae*, at 2 months old, which further provides protection against common bacterial pathogens. As a result, empirical testing and treatment give way to more selective evaluations above 2 to 3 months old.

### Clinical Features

History taking should focus on the length of illness, presence of localizing symptoms (eg, headache and neck pain [meningitis or encephalitis] or ear pain [otitis media]), exposure to persons with serious illness, and any pertinent past medical history. For infants younger than 28 days old, document birth history, including the presence of potentially transmittable maternal infections (HSV or group B streptococcus). Document immunization status, sick contacts, use of antipyretics before evaluation, and prior use of antibiotics. Defervescence after acetaminophen administration has not been shown to reliably exclude bacteremia in children of any age. Prior antibiotic use may mask the classic findings in diseases, such as meningitis. Cough and congestion may suggest pneumonia or viral upper respiratory infection, whereas a harsh, barking, or seal-like cough is often a predominant complaint in viral laryngotracheitis (croup). Parents may report vomiting and diarrhea as a component of gastroenteritis or the presence of sore throat and lymphadenopathy with viral or streptococcal pharyngitis. Decreased oral intake or decreased urine output is a frequent complaint in gastroenteritis but may also be seen in patients with stomatitis, because the painful aphthous ulcerations in the mouth make fluid intake difficult. Any history of lethargy, irritability, or altered mental status can be elicited with severe dehydration but may be seen in life-threatening conditions, such as meningococcemia, Rocky Mountain spotted fever, and toxic shock syndrome (TSS).

The physical examination of the febrile child should begin with a complete set of vital signs, including pulse oximetry. Hypoxia or significant respiratory distress manifested by tachypnea, grunting respirations, nasal flaring, or retractions may accompany sepsis or
pulmonary infection. Stridor can be seen with croup but also with retropharyngeal abscess, epiglottitis, or bacterial tracheitis. Note signs of shock, such as hypotension and poor peripheral perfusion, should be noted. Children typically mount a tachycardic response to fever, and hypotension is often a late and dire finding. Tachycardia is often due to the fever itself, but tachycardia out of proportion to the degree of fever can be seen with early shock, myopericarditis, and dehydration. Estimations of heart rate increase based on fever in infants younger than 12 months old (ie, heart rate increases linearly by 9.6 beats/minute with each 1°C increase in body temperature) should be used with caution, and clinical signs of sepsis should be evaluated before attributing tachycardia to fever alone. Once oxygenation, ventilation, and perfusion have been assessed and deemed adequate, the physical examination should focus on a thorough search for focal infection. In young infants, particularly those younger than 3 months old, and in children who lack immunocompetence, fever may be the only presenting sign of SBI, including meningitis. The physical examination in this age group is sufficiently insensitive to exclude SBI, and emergency clinicians should not be falsely reassured by a normal physical examination in small children.

Diagnostic Testing

Numerous laboratory and radiographic studies can be used to evaluate the febrile child. In general, testing should be directed at identification of the source of infection or evaluation for complications. Several guidelines exist for the evaluation of febrile children, although there is marked variation in adherence to these guidelines. Office-based practitioners have been found to follow published guidelines only 42% of the time in the evaluation of febrile children. Clinicians with less experience and those based in the hospital tend to order more tests compared with more experienced clinicians and those practicing in an office setting. Use of institutional clinical decision rules and guidelines can help streamline appropriate testing.6-7

White Blood Cell Count

An elevated white blood cell (WBC) count (>15,000/mm³) can be an indicator of bacteremia but is also present in many viral illnesses. Leukopenia (<5000/mm³) can also be a sign of SBI or early sepsis. Pneumococcal infection is classically associated with leukocytosis, whereas infection with N. meningitidis and H. influenzae may be present even with normal WBC counts. Lee and colleagues found that the rate of pneumococcal bacteremia increased from 0.5% in highly febrile children (>102.2°F [39.0°C]) with a WBC count between 10,000 and 15,000/mm³ to 3.5% if the WBC count was 15,000 to 20,000/mm³ and up to 18% with a WBC count above 30,000/mm³. More extreme leukocytosis is associated with an increased risk of bacterial infection, particularly lobar pneumonia and a WBC count of above 25,000/mm³ should prompt consideration of a chest radiograph unless another definitive source is apparent.8

The WBC differential diagnosis has also been used to risk stratify febrile children in various models; an increase in polymorphonuclear leukocytes increases the risk of bacterial disease. A rise in polymorphonuclear leukocytes is also seen early in some viral infections. An absolute neutrophil count (ANC) above 10,000/mm³ suggests increased risk of pneumococcal bacteremia in febrile children (0.8% for children with an ANC below 10,000/mm³ vs. 8% for children with an ANC above 10,000/mm³). Routine screening of all febrile children with bloodwork has not been shown to be cost effective in the post-vaccination era. The vast majority of acute febrile illness is due to self-limited viral infection. If the decision is made on clinical grounds to obtain a WBC and it is abnormal (<5,000/mm³ or >15,000/mm³) or the ANC is greater than 10,000/mm³, then screening for occult bacteremia with a blood culture is advised, understanding that leukocytosis is neither perfectly sensitive nor specific for bacterial illness. Treatment of incompletely immunized children who have a WBC more than 15,000/mm³ with parenteral ceftriaxone is appropriate.

Inflammatory Markers. Both C-reactive protein (CRP) and procalcitonin have been studies as markers of bacterial infection. The utility of the measurement of inflammatory markers is dependent on the cutoff level assigned for clinical significance with lower values having higher sensitivity but lower specificities. Both CRP and procalcitonin appear to be more sensitive and specific than the WBC alone, although the lack of widespread availability limits the usefulness of procalcitonin clinically at this time.6-11

Blood Culture

Many centers obtain blood for culture during intravenous (IV) catheter placement after sterile preparation of the skin has been performed. Although this technique has the advantage of eliminating a second venipuncture solely to obtain blood for culture, the rates of contamination with this technique have been shown to be higher than a sterile straight stick in children (9.1% vs. 2.8%). The risks of contamination should be weighed against the ability to obtain blood through a separate venipuncture. The yield of a single blood culture in infants and small children is actually good. The routine sending of more than one sample is generally not needed, and bacteremia is often accurately detected even if only 0.5 to 1 mL of blood is obtained. The advent of automated blood culture systems has led to the identification of true pathogens more quickly than by traditional methods, often within 24 hours. Pathogens isolated in the first 24 hours are more likely to be true pathogens than are bacteria isolated after 24 hours.12

Urinalysis and Urine Culture

UTIs are common causes of bacterial illness in febrile children, occurring in 5% of infants 2 to 24 months old with fever 100.4°F (38.0°C) or higher. Accurate documentation of UTI is imperative both to diagnose the cause of a fever and to identify those infants who need follow-up radiographic imaging to exclude anatomic abnormalities that will predispose them to further infection. It is currently recommended that febrile infants with documented UTIs undergo renal ultrasonography to evaluate for hydronephrosis or rare complications, such as renal or perirenal abscesses. Voiding cystourethrogram is not indicated after the first febrile UTI in children unless renal ultrasonography reveals evidence of high-grade vesicoureteral reflux or scarring.

The only reliable method to obtain urine in a non–toilet-trained child is bladder catheterization or suprapubic aspiration. Bladder catheterization is the preferred method in almost all cases. Bag collection of urine is notoriously unreliable; up to 85% of cultures from bag specimens will be falsely positive (defined as a culture growing a single organism with >10³ colony-forming units [CFUs]/mL or a mix of two or more organisms), which then places these children at risk for unneeded, potentially painful, and expensive follow-up diagnostic testing and antibiotics. A clean catch urine specimen is appropriate for toilet-trained children.

UTI is defined as the combination of bacteriuria and pyuria. Bacteriuria in the absence of WBCs on microscopic examination represents asymptomatic bacteriuria. Urine is typically analyzed with a dipstick, followed by microscopic analysis of a centrifuged specimen of urine. An “enhanced” urinalysis, which is examination with a hemocytometer of an unspun specimen of urine for pyuria (defined as >10 WBCs per high-power field) or the
presence of any bacteria per high-power field in Gram stain of unspun urine has a negative predictive value of 99.8%, perhaps making urine culture unneeded if pyuria and bacteriuria are absent by use of the enhanced urinalysis method. However, many centers are not using this enhanced method. Because dipstick and microscopic analysis have lower sensitivities, most experts recommend sending urine for culture in high-risk groups (febrile girls <24 months old, uncircumcised boys <12 months old, and circumcised boys <6 months old).

A positive urine culture is defined as the growth of more than 50,000 CFU/mL of a single uropathogen in urine obtained via catheterization or suprapubic aspirate.

Lumbar Puncture

A sample of cerebrospinal fluid (CSF) should be obtained from any child with signs and symptoms of meningitis. Fluid should be obtained with the smallest pencil-point or noncutting spinal needle possible (typically a 22-gauge spinal needle) and sent for cell counts, manual differential diagnosis, Gram staining, culture, and measurement of CSF protein and glucose concentrations. Meningoencephalitis due to HSV is a potential cause of fever, particularly in children; if suspected, CSF should be sent for HSV polymerase chain reaction (PCR) testing. The CSF in bacterial meningitis typically contains more than 1000 WBCs/mL, although there is considerable overlap in the CSF profile of bacterial and viral meningitis, making a determination of viral or aseptic meningitis difficult on the basis of CSF parameters, such as cell count, protein, and glucose; thus, CSF culture of a pathogenic bacterium is the “gold standard.” A prediction rule has been developed and validated to differentiate bacterial from aseptic meningitis in children 29 days to 19 years old who have CSF pleocytosis. Children without any of the following criteria have a low risk (0.1%) of bacterial meningitis: positive CSF Gram stain, CSF ANC of 1000 cells/mL or more, CSF protein concentration of at least 80 mg/dL, peripheral blood ANC of 10,000 cells/mL or more, and history of seizure before or at the time of presentation. This may obviate the need for empirical antibiotic therapy and hospital admission in some children who are at low risk for bacterial meningitis.

Contraindications to lumbar puncture include cellulitis over the proposed site of puncture, cardiopulmonary instability, bleeding diathesis, or platelet count below 50,000/µL, focal neurologic deficits, and signs of increased intracranial pressure, including papilledema. In these patients, lumbar puncture should be deferred until the child is stable, and blood should be obtained for culture while the child is treated empirically, recognizing that up to 50% of children with meningitis will not have bacteremia.

CSF contaminated by blood, or a traumatic lumbar puncture, can make interpretation of cell counts and differential diagnoses difficult. In these cases, fluid should be obtained for Gram stain and culture and the child hospitalized and treated presumptively for meningitis until culture data are available. Risk factors for a traumatic lumbar puncture include operator experience, excessive patient movement during the procedure, multiple attempts, advancement of the needle with the stylet in place, and lack of local anesthesia.

Stool Studies

Stool studies are indicated in patients in whom bacterial gastroenteritis may be a cause of fever. A stool guaiac test for blood as well as Gram stain for WBCs should be performed. Presence of more than 5 WBCs per high-power field in the stool of a febrile child should trigger a culture of stool for Salmonella, Shigella, Campylobacter, enterotoxigenic E. coli, and Yersinia species. Patients with sickle cell disease are at particular risk for focal complications, such as osteomyelitis from Salmonella infection (see Chapter 171).

Chest Radiography

Chest radiographs may be useful in the evaluation of the febrile child and are indicated when hypoxemia, respiratory distress, tachypnea, or focal findings on lung examination are present. Children younger than 6 months old may present with tachypnea as the sole finding of bacterial pneumonia. Truly occult pneumonia can also occur in a small percentage of children, particularly in the highly febrile child (>102.2°F [39.0°C]) without apparent source of fever and an elevated ANC. Studies done prior to universal vaccination against pneumococcus demonstrated a relatively high rate of pneumonia in highly febrile children who had leukocytosis more than 20,000/mm³ (26%). Since the advent of universal vaccination, the number of occult pneumonias has declined (15% to 9%) but is not yet low enough to recommend not obtaining radiographs on highly febrile children with leukocytosis or elevated ANC and no other apparent source of infection.

Rapid Viral Antigen Testing

Many clinical laboratories have the ability to perform rapid viral antigen testing for such common pediatric viral illnesses as influenza A and B and RSV. The presence of a viral “source” for the fever in an ill child may obviate the need for expensive, painful, and lengthy diagnostic evaluations for bacterial processes. Of patients aged 2 months to 21 years old who present with classic signs and symptoms of influenza, more than half have been shown to have positive rapid assays for influenza, leading to fewer antibiotics prescribed. A large multicenter trial of febrile infants 60 days old or younger revealed a decreased risk (2.5% vs. 11.7%) if the infant was influenza positive.

RSV is also a frequent cause of fever in children. As previously noted, RSV decreases but does not completely eliminate the risk of SBI in children. This is especially true of UTI in infants younger than 28 days old. Routine testing for RSV has not been shown to affect outcome at the individual patient level. Based on this data, it is reasonable to consider a selective, de-escalated evaluation (ie, urine and urine culture) of well-appearing infants who have positive viral testing in the ED given the exceedingly low rates of bacteremia and meningitis. Ill-appearing infants or neonates (28 days old and younger) should still undergo a full evaluation for SBI.

Approach to the Febrile Infant and Child

The initial approach to any child with a febrile illness is a rapid assessment for evidence of cardiopulmonary compromise or shock. Significant respiratory distress, hypoxemia unresponsive to supplemental oxygen, or altered mental status may necessitate intubation by rapid sequence induction and mechanical ventilation. Evidence of shock (poor perfusion, hypotension, altered mentation) should be aggressively treated with fluid resuscitation. An IV or intraosseous line should be placed, and the initial resuscitative fluid should be 20 mL/kg of isotonic crystalloid. This should be repeated to a total of 60 mL/kg over 60 minutes if signs of hypovolemia persist, after which vasopressor therapy (dopamine 1 to 20 µg/kg/min or norepinephrine 0.1 to 3 µg/kg/min titrated to blood pressure) should be considered.

Every effort should be made to obtain appropriate specimens for culture (blood and urine), even in the critically ill child, before antibiotic administration. Lumbar puncture may be deferred in the critically ill child until stabilization occurs. Empirical antibiotic therapy should be directed at the most likely causative
organisms based on age. Sterilization of the CSF starts to occur once antibiotic administration has been initiated—within 15 minutes to 2 hours in patients with meningococcal meningitis and within 4 to 10 hours in patients with pneumococcal meningitis. However, antibiotics should not be delayed awaiting successful sterilization of the CSF, which may occur within 4 to 10 hours in patients with pneumococcal meningitis and once antibiotic administration has been initiated—within 15 hours.

Infants 0 to 28 Days Old

Children presenting with temperature of 100.4°F (38.0°C) or higher who are younger than 28 days old are at particularly high risk for bacterial illness, with rates as high as 12%.

Often, fever is the only manifestation of potentially life-threatening disease, with other signs and symptoms being exceedingly subtle. This has led to an aggressive approach to diagnostic testing, empirical antibiotic therapy, and hospitalization in this age group, even if the child appears well.

Children in this age group often present with nonspecific complaints, such as irritability, lethargy, poor feeding, and grunting. Besides fever, other signs of serious illness include a bulging fontanel, mottled extremities, petechiae, and tachypnea. Bacterial pathogens in this age group include group B streptococcus, L. monocytogenes, N. meningitidis, S. pneumoniae, and E. coli. Viral pathogens, including RSV and HSV, are also important considerations. Neonatal HSV infection carries a high degree of morbidity and mortality and should be considered in any febrile neonate with a maternal history of genital herpes, or who appears ill, presents with fever and seizure, has cutaneous vesicles on physical examination, or evidence of transaminitis or coagulopathy. HSV meningoencephalitis should also be considered in patients with fever and CSF pleocytosis but a negative CSF Gram stain. The highest risk period for HSV disease is between 2 and 12 days old (Fig. 166.2). Other noninfectious causes of a septic-appearing neonate include the acute salt-wasting crisis associated with congenital adrenal hyperplasia and undiagnosed ductal-dependent congenital heart disease.

Because of the high risk of bacterial pathogens and the difficulty in clinical assessment of children younger than 28 days old (neonate), these patients require an aggressive diagnostic evaluation, including a complete septic evaluation. This consists of a complete blood count (CBC) with differential diagnosis, blood culture, urinalysis and urine culture, and lumbar puncture. Lumbar puncture is indicated in this age group even in the presence of a UTI because of the risk of concomitant meningitis. All neonates should be admitted to the hospital with empirical antibiotics until culture data become available. Appropriate parenteral antibiotic regimens include ampicillin (100 mg/kg/24 hours divided every 6 hours) plus either gentamicin (5 mg/kg/24 hours divided every 8 to 12 hours) or cefotaxime (150 mg/kg/24 hours divided every 8 hours). Ceftriaxone should be avoided in infants younger than 28 days old because of a theoretic risk of inducing acute bilirubin encephalopathy as ceftriaxone causes bilirubin to be displaced from its protein binding sites. Empirical acyclovir should be added if risk factors for HSV disease exist (60 mg/kg/24 hours divided every 8 hours).

Infants 29 to 90 Days Old

Although there is a relative consensus as to the evaluation and management of febrile infants younger than 28 days old, there is debate about the appropriate evaluation for the slightly older febrile infants. Ill-appearing children of any age should have a complete sepsis evaluation performed and be admitted to the hospital with empirical antibiotic therapy. Appropriate antibiotic therapy for high-risk children includes coverage of neonatal pathogens, such as L. monocytogenes and group B streptococci, as well as coverage against H. influenzae, N. meningitidis, and S. pneumoniae. Ampicillin, 50 to 100 mg/kg every 6 hours, plus cefotaxime, 50 mg/kg every 8 hours parenterally, is one option. Vancomycin, 10 to 20 mg/kg IV every 6 to 8 hours, should be considered if S. pneumoniae resistant to penicillins and cephalosporins is suspected.

Various strategies (herein referred to as the Rochester, Philadelphia, and Boston criteria) for the evaluation of well-appearing children have been reported, compared, and restated in the literature. Each strategy has unique features, including the definition of fever (100.4°F [38.0°C] vs. 100.8°F [38.2°C]), the study population (0 to 3 months old, 1 to 2 months old, and 1 to 3 months old), the clinical and laboratory variables studied, and the disposition (hospitalization with or without antibiotics or outpatient treatment with or without antibiotics). Each strategy seeks to identify a set of low-risk criteria that, if met, will allow less aggressive treatment or the withholding of empirical antibiotic therapy. The three main strategies are highlighted in Table 166.2. Baraff synthesized the recommendations of the Rochester, Philadelphia, and Boston criteria into an algorithm for the management of the previously healthy febrile infant 29 to 90 days old (Fig. 166.3). To be low risk, the child had to have been previously healthy with an uncomplicated nursery stay, to be nontoxic clinically, and to have no focal source of bacterial infection. Low-risk laboratory criteria in this schema included a normal WBC count (between 5000 and 15,000 WBCs/mm3), fewer than 1500 bands/mm3, normal urinalysis (negative Gram stain and <5 WBCs per high-power field), and negative CSF Gram stain and cell counts (<8 WBCs/mm3), if obtained. When diarrhea was present, fewer than 5 WBCs per high-power field was the threshold for low risk.

Once the child is deemed to be at low risk by these criteria, two options are available to the clinician on the basis of the Philadelphia and Boston criteria. One management strategy calls for a CBC, blood culture, urinalysis, and urine culture. If the results reveal the patient to be at low risk, the child may be discharged without antibiotics with close outpatient follow-up. If results are abnormal, the patient should receive a lumbar puncture and antibiotics. Another option, based on the Boston criteria, calls for a complete sepsis evaluation, including lumbar puncture, followed by empirical treatment with ceftriaxone (50 mg/kg IV or intramuscularly [IM]) and reevaluation within 24 hours. Overall, antibiotics should not be administered unless a complete sepsis evaluation is performed, including a lumbar puncture. Otherwise, if a lumbar puncture is not initially performed and the child returns for reevaluation and a lumbar puncture is subsequently performed with the finding of CSF pleocytosis, pretreatment
with antibiotics makes interpretation of culture results difficult. Thus a child with a possible viral process may be subjected to outpatient treatment, the following must be met: white blood cell (WBC) count 5,000 to 15,000 cells/mm³, urinalysis is negative, lumbar puncture without pleocytosis or bacteria on Gram stain, able to return for care if necessary, reliable outpatient follow-up, no focal infection present (ie, cellulitis, omphalitis), and chest radiograph and stool studies negative if obtained. abx, Antibiotics.

Fig. 166.3. Sample algorithm for the management of febrile infants younger than 3 months old. To be eligible for outpatient treatment, the following must be met: white blood cell (WBC) count 5,000 to 15,000 cells/mm³, urinalysis is negative, lumbar puncture without pleocytosis or bacteria on Gram stain, able to return for care if necessary, reliable outpatient follow-up, no focal infection present (ie, cellulitis, omphalitis), and chest radiograph and stool studies negative if obtained. abx, Antibiotics.

Infants 3 to 36 Months Old

Most cases of fever in children 3 to 36 months old represent self-limited viral illnesses. Common causes of fever in this age group include viral upper respiratory infections, croup, bronchiolitis, stomatitis (typically caused by HSV or coxsackievirus), gastroenteritis, roseola, and fifth disease (parvovirus B19 infection). Focal infections, such as pyelonephritis, periostial cellulitis, bacterial pharyngitis (group A streptococcus), septic arthritis, retropharyngeal abscess, meningitis, and bacterial pneumonia, also become common in this age group. Typically, these focal infections are apparent on the basis of history and physical examination findings, and diagnostic testing and treatment should be directed accordingly.

The history in this age group should focus on the duration of illness, associated symptoms that may focus the evaluation, immunization history (particularly vaccination for H. influenzae type B and pneumococcus), and sick contacts. A thorough physical examination is essential to rule out serious focal infection, such as meningitis. Young children may demonstrate inconsolable irritability or lethargy as the sole manifestation of meningitis; furthermore, classic meningeal signs, such as nuchal rigidity, are seen in less than 27% of infants (0 to 6 months old) with bacterial meningitis.

Prior research has focused on assessment of children in this age group for the presence of occult bacteremia. It was found that a small percentage of highly febrile children (>102.2°F [39.0°C]) 3 to 36 months old were bacteremic. These children were noted to be highly febrile but lacked any localizing signs of infection. No historical or physical examination findings were sufficiently sensitive or specific to identify cases of occult bacteremia, making universal diagnostic testing necessary. A typical evaluation included a CBC and blood culture, and empirical antibiotic therapy was prescribed for children with WBC counts above 15,000/mm³. Empirical antibiotics were justified on the basis of studies that revealed treatment with antibiotics prevented focal sequelae of bacteremia, such as meningitis and shortened the duration of fever. Before the advent of almost universal immunization against
S. pneumoniae, the rate of occult bacteremia was approximately 3%, and although pneumococcal bacteremia resolved without therapy up to 75% of the time, a small proportion of children had sepsis or focal infections, such as meningitis. Pneumococcal meningitis has a high degree of morbidity and mortality, including permanent neurologic disability, hearing loss, and death.

Since the advent of PCV7 (conjugate pneumococcal vaccine) and most recently PCV13, the number of invasive pneumococcal infections caused by vaccine-serogroup isolates among eight children's hospitals in the United States has decreased more than 75% among children younger than 24 months old. Because of the decline in invasive pneumococcal disease brought on by vaccination, the cost-effectiveness of mandatory blood testing has been called into question. The cost-effectiveness of various management strategies have been evaluated: no evaluation, relying on clinical judgment, blood culture, blood culture plus empirical antibiotics, WBC count plus blood culture and empirical antibiotics, and WBC count plus selective blood culture for WBC counts above 15,000 and empirical antibiotics. For rates of pneumococcal bacteremia greater than 1.5%, obtaining a WBC count plus selective blood culture and empirical antibiotics has been shown to be the most cost-effective approach, whereas for rates of pneumococcal bacteremia less than 0.5%, strategies that use empirical testing and treatment have not been found cost-effective. They concluded that at lower rates of bacteremia, clinical judgment is more useful in selecting out high-risk populations who might benefit from selective testing and treatment. Although the incidence of pneumococcal bacteremia has declined in infants 3 to 36 months old because of the aggressive campaign to vaccinate, infants 3 to 6 months old have not yet completed the primary series of immunizations against S. pneumoniae and to a lesser extent H. influenzae. Despite being “incompletely vaccinated” at this age, the rate of bacteremia is exceedingly low, arguing against routine screening in this age group. The 13-valent conjugate pneumococcal vaccine (PCV-13) for routine childhood vaccinations provides expanded coverage. The additional six serotypes included in PCV13 were responsible for more than 60% of the cases of invasive pneumococcal disease in the years preceding the release of the updated vaccine schedule.

Despite these vaccine advances, there are approximately 90 serotypes that are capable of infecting humans, and continued bacterial surveillance is necessary to ensure that other serotypes do not rise in incidence to fill the void left by vaccination. No clinical prediction algorithm correctly identifies all patients with meningococcal disease. Additional signs and symptoms that may suggest meningococemia are purpuric rash, bandemia, limb pain, and exposure to a person with the disease. An appropriate flow diagram for the evaluation of febrile infants 3 to 36 months old is presented in Figure 166.4.

**Children 3 Years Old to Adulthood**

The incidence of occult bacteremia decreases after 3 years old. Focal infections such as streptococcal pharyngitis, septic arthritis, pneumonia, peritonitis, abscess (most often in adolescents), and cellulitis become more common. Viral pathogens are also common, such as infectious mononucleosis. Infection with atypical pathogens, such as Mycoplasma pneumoniae, should also be considered in children presenting with pneumonia. Skin infections secondary to community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) are also becoming more common. Community-acquired MRSA occurs in all age groups but has clustered among such children as wrestlers (associated with contaminated wrestling mats) and football players (infected equipment). This diagnosis should be considered in all children who present with pyogenic skin infection and skin abscesses. Appropriate therapy includes incision and drainage of the abscess cavity. Antibiotic therapy in addition to incision and drainage for simple abscesses has not been shown to hasten resolution of the infection but should be considered for patients with large abscesses (>5 cm), with cellulitis, or with fever. Antibiotic selections should be based on local resistance patterns, but could include trimethoprim-sulfamethoxazole or clindamycin for younger children and doxycycline for children 8 years old or older.

There is a second peak in incidence of meningococcal disease in adolescent children with an attack rate of 1.2 infections per 100,000 population. As opposed to infants, adolescents with meningococcal infection are more likely to present with meningococcemia (40% vs. 20%) and shock (69% vs. 27%) and to have a fatal outcome (22.5% vs. 4.6%). Meningococcal often manifests with one of three clinical syndromes: meningitis, bacteremia, or a combination of the two. College students residing in dormitories are at particular risk for infection, with attack rates of 3.2/100,000 population.

Meningococcal infection is often rapidly progressive, presenting with fever, headache, and a stiff neck. Shock, altered mental status or frank coma, petechiae or purpura, seizures, and myalgias are also seen. Some of the first signs of meningococcal infection include leg pain, cold hands and feet, and abnormal skin mottling. Children exposed to a patient with meningococcemia, particularly those with close contact with nasopharyngeal secretions, and who have any of the presenting signs should receive a full septic evaluation, admission to the hospital, and empirical treatment with antibiotics until results of blood and CSF cultures are known. Appropriate initial therapy for children suspected of having meningococcal infection is ceftriaxone 100 mg/kg IV.

In January 2005, the U.S. Food and Drug Administration (FDA) approved the quadrivalent meningococcal conjugate vaccine (Menactra) for use in adolescents. This vaccine is a polysaccharide-protein conjugate directed against the four serotypes that cause most cases of invasive meningococcal disease in humans. The Advisory Committee on Immunization Practices recommends vaccination of adolescents at their 11- or 12-year-old well-child checkup, and the American Academy of Pediatrics (AAP) has also advised that all college freshmen living in dormitories be vaccinated. Use of the vaccine is associated with a 67% decrease in invasive disease and a 66% decrease in carriage rates. Younger children with anatomic or functional asplenia, those with complement component deficiencies, and children who travel reside in other countries where the disease is hyperendemic should be vaccinated. Based on age, a number of vaccines for prevention of meningococcal disease are available (www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html).
Febrile Seizures

Febrile seizures are a common cause of convulsions in children younger than 5 years old. They are defined as a seizure accompanied by fever without the presence of CNS infection. They typically occur in infants and children 6 months to 5 years old. It is thought that the at-risk period is the rapid rise or defervescence of a fever, rather than the absolute height of the fever. Many parents worry about the subsequent risk of epilepsy after a febrile seizure, although studies have borne out that the risk is only slightly increased. The risk of epilepsy in the general population is thought to be 0.5% to 1%, whereas the risk in a patient who has had a febrile seizure is 1% to 2%. Although they are generally benign in course, febrile seizures can rarely be the presenting complaint of infants and children with CNS infection, such as meningitis. Febrile seizures are classified as either simple or complex. Simple febrile seizures are brief (<15 minutes), single, and nonfocal or generalized tonic-clonic. Complex febrile seizures are prolonged, recurrent (more than one within 24 hours), focal, prolonged, or occur outside the typical age range.

Differentiation of a benign febrile seizure from one that heralds CNS infection can be difficult. The AAP has published consensus guidelines for the evaluation and management of febrile seizures. Laboratory and radiographic evaluation should be directed at finding the source of the fever, not driven by the seizure itself. The AAP suggests that a lumbar puncture be performed in any child with signs of meningeal irritation after the first febrile seizure and be considered in symptomatic children who are incompletely immunized or have received prior antibiotic therapy.

Routine referral for neuroimaging or electroencephalography is not indicated. There is also no role for antiepileptic therapy after a single febrile seizure. Retrospective studies have shown that the incidence of meningitis after the simple or complex febrile seizures is exceedingly low and that infants with meningitis will demonstrate signs of sepsis or meningitis after the seizure, making empirical lumbar puncture based solely on a febrile seizure unnecessary.

Parents should be warned that recurrence is common and is inversely related to age of first febrile seizure and height of the fever. Overall 33% of children who have a febrile seizure will have another one, and that 75% of these will occur within a year. If the child is younger than 1 year old, the recurrence is 50%, and children presenting with temperatures of 101.3° F (38.5° C) has a 35% chance of recurrence versus 13% at 104° F (40° C).

Fever and Petechiae

The presence of a petechial rash in the setting of a febrile illness is concerning for the possibility of meningococcal infection, although the vast majority are due to a viral cause. The incidence of meningococcal infection has been found to be 7% to 11% in patients hospitalized with fever and petechiae. The rate of bacteremia of any cause was found to be much lower (1.9%) in an ED population. The differential diagnosis of fever and petechiae also includes disseminated intravascular coagulation, Rocky Mountain spotted fever, pneumococcal bacteremia, *Streptococcus pyogenes* infection, various viral infections, idiopathic thrombocytopenic purpura, Henoch-Schönlein purpura, and leukemia. Petechiae can also be caused mechanically from a tourniquet, retching, or violent coughing. Petechiae due to vomiting or coughing are typically confined to the skin above the nipple line, but petechiae caused by SBI can have any distribution.

Because of the risk of serious illness in children with fever and petechiae, blood should be obtained for CBC, CRP, and culture. Patient with associated pharyngitis should undergo testing for group A streptococcus infection. Among patients presenting to a pediatric ED with temperature higher than 100.4° F (38.0° C) and petechiae, an abnormal WBC count (<5000 WBCs/mm³ and >15,000 WBCs/mm³) or abnormal coagulation studies have been shown to be predictive but not diagnostic of invasive bacteremia. Well-appearing children with normal WBC and coagulation studies were exceedingly unlikely to have invasive bacteremia. In their study, only two well-appearing children had bacteremia (*S. pneumoniae*), and this study was done in the pre-Prevnar era. It is recommended that children with fever and petechiae, and an elevated or depressed WBC, high band count, or elevated CRP be admitted and treated for presumptive bacterial infection until the results of the blood culture are available. Well-appearing children with normal laboratory parameters can be discharged without antibiotic therapy with close outpatient follow-up.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is one of the most common vasculitides in childhood and should be considered in any infant or child with prolonged fever (greater than 4 days). A more complete discussion of Kawasaki disease can be found in Chapter 170. Accurate diagnosis is important because the main complication of Kawasaki disease is the development of coronary artery aneurysms. Some patients will present with “incomplete Kawasaki disease,” which occurs when not all diagnostic criteria are met. Despite the lack of classic findings, these children are still at risk for coronary complications. Laboratory abnormalities found in cases of Kawasaki disease include leukocytosis, thrombocytosis (platelet counts as high as 1,000,000/mm³), and evidence of systemic inflammation with elevation in the erythrocyte sedimentation rate and CRP level.

Children with suspected Kawasaki disease should be hospitalized and receive therapy with intravenous immune globulin (IVIG; 2 g/kg infused during 10 to 12 hours) and aspirin (initial dose 80 to 100 mg/kg daily divided every 6 hours). Pediatric cardiology consultation for echocardiography is also indicated.

Toxic Shock Syndrome

TSS refers to the toxin-mediated clinical syndrome that occurs from *Staphylococcus aureus*, although a similar illness is caused by group A streptococci. The toxin implicated in TSS is an exotoxin termed TSS toxin 1. The syndrome is classically associated with tampon use by menstruating women, although cases also occur in males and prepubertal girls from other sources of infection with *S. aureus*.

Clinical manifestations of TSS include fever (>102° F [38.9° C]), hypotension, diffuse erythroderma, and multisystem involvement. Patients may present with vomiting or diarrhea, severe myalgias, oropharyngeal hyperemia, or altered mental status. Laboratory abnormalities are common and include elevated creatine kinase, elevated blood urea nitrogen or creatinine, transaminits, and thrombocytopenia. The Centers for Disease Control and Prevention (CDC) has developed a set of findings for case definition (Box 166.1).

Treatment of TSS involves fluid resuscitation, because these patients typically have immense requirements and antistaphylococcal antibiotic therapy with clindamycin (25 to 40 mg/kg per day in three divided doses) and vancomycin (40 mg/kg per day IV in four divided doses).

Fever in Children With an Underlying Chronic Medical Illness

Oncology Patients

Children with cancer, particularly those undergoing treatment with cytotoxic chemotherapy, are at particular risk for sepsis and...
bacterial infection. These life-threatening infections are most common during periods of profound neutropenia. Neutropenia is defined as an ANC of less than 500/mL or an ANC of less than 1000/mL that is falling. Children with cancer also frequently have indwelling catheters, predisposing them to surgical line infections.

Causative organisms include both gram-positive and gram-negative bacteria. Staphylococci and streptococci as well as *Pseudomonas* are frequent pathogens. Often, patients with focal infection may not present with classic signs because of their leukopenia. Focal infections specific to cancer patients include stomatitis and typhlitis, which is a necrotizing enterocolitis of the terminal ileum and cecum.

Children presenting with fever and possible neutropenia require prompt evaluation with a goal of arrival to antibiotic therapy of less than 60 minutes. Blood should be obtained for a CBC and manual differential diagnosis as well as culture. If a central line infection is suspected, a separate culture specimen from the line should be obtained. Once appropriate laboratory studies are obtained, empirical antibiotic therapy should be initiated without waiting for the laboratory results. Appropriate monotherapy antibiotic regimens include cefepime, 50 mg/kg IV every 8 hours, and cefazidime, 50 mg/kg IV every 8 hours. Vancomycin, 10 to 20 mg/kg every 6 to 8 hours, should be added for antistaphylococcal coverage in children with suspected central line infections or skin and soft tissue infections. Children with fever and neutropenia are rarely treated as outpatients; if so, ceftriaxone 50 mg/kg IV should be given every 24 hours with close follow-up.

**Patients With Acquired Immunodeficiency Syndrome**

Children with the acquired immunodeficiency syndrome (AIDS) are at risk for bacterial infection due to a whole host of different organisms—some common, some uncommon. Infections specific to AIDS include cryptococcosis and infection with *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*, and *Pneumocystis jiroveci* (*carinii*). Viral infections, such as cytomegalovirus and Epstein-Barr virus infections, are also common.

Laboratory evaluation should be directed by the history and physical examination. Early initiation of broad-spectrum antibiotic therapy is warranted.

**Sickle Cell Disease**

Fever in children with sickle cell disease are at particular risk for overwhelming infection. In fact, infection is the most common cause of sickle cell–related death, occurring in up to 40% of patients with sickle cell disease who die. Recurrent episodes of splenic infarction lead to functional asplenia early in life. Thus, these patients are at particular risk for infection with encapsulated organisms, including *S. pneumoniae* and *H. influenzae*. Because of this risk of bacterial disease, it is recommended that all children with sickle cell disease be completely immunized. Prophylaxis with penicillin is recommended in children younger than 5 years old, after which it can be safely discontinued in children who have not had a prior severe pneumococcal infection or surgical splenectomy. The dose of penicillin is 125 mg orally twice daily until 3 years old (at about 14 kg) and 250 mg orally twice daily after 3 years old.

High-risk criteria for bacterial infection include toxic appearance, temperature higher than 104°F (40°C), abnormal WBC count (<5000 or >30,000 WBCs/mm³), and noncompliance with penicillin prophylaxis. Sickle cell patients are at particular risk for *Salmonella* osteomyelitis. All patients presenting with a temperature higher than 100.4°F (38.0°C) and sickle cell disease should have a blood specimen drawn for CBC, reticulocyte count, and culture. A reticulocyte count is important, because many infections (eg, parvovirus B19) can induce life-threatening aplastic crisis. Infection also predisposes children with sickle cell disease to acute chest syndrome. Common causes of infection include *Chlamydia pneumoniae*, *M. pneumoniae*, RSV, *S. aureus*, and *S. pneumoniae*. Further laboratory and radiographic evaluation should be directed by the presenting history and physical examination findings.

As defined earlier, high-risk patients should be admitted for further evaluation and antibiotic therapy. Low-risk patients may be treated with a single dose of IV or IM antibiotics, typically ceftriaxone 50 mg/kg, and discharged to close outpatient follow-up. All patients should be reevaluated within 24 hours or sooner if the clinical condition deteriorates.

Osteomyelitis typically is manifested with fever and bone pain. As patients with sickle cell disease may have frequent bone pain due to vaso-occlusive crisis, the diagnosis often can be difficult. All patients should have a blood specimen drawn for CBC with differential diagnosis, erythrocyte sedimentation rate, and culture; a radionuclide bone scan or magnetic resonance imaging (MRI) may help localize the infection. If *Salmonella* infection is suspected, a stool sample should be sent for culture.

**Congenital Heart Disease**

Children with congenital heart disease are at high risk for cardiovascular complications in the setting of febrile illness. Often, relatively minor viral illness can produce significant changes in
CHAPTER 166  Pediatric Fever

**Pediatric Fever**

Gentamicin, 3 mg/kg IV divided every 8 hours, if shorter treatment duration (2 weeks) is desired. See Chapter 170 for a more complete discussion.

**Ventriculoperitoneal Shunts**

Children presenting with fever in the setting of ventriculoperitoneal shunts are at risk for shunt infection. If shunt infection is suspected, based on the presence of altered mental status or signs of meningismus, neurosurgical consultation should be obtained and a sample of CSF obtained. This is typically accomplished by sterile aspiration of fluid from the shunt reservoir. *S. aureus* and *Staphylococcus epidermidis* are the usual causative organisms. If altered mental status is present, a computed tomography (CT) scan should be obtained to assess ventricular size. Children with suspected shunt infection are typically managed as inpatients, and antibiotics should begin as soon as possible.
Part V
Special Populations
Section One
The Pediatric Patient

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

- Fever is the most common complaint among pediatric patients presenting to the emergency department (ED), although rates of bacterial illness are lower since the advent of universal vaccination for Haemophilus influenzae type b and Streptococcus pneumoniae. Serious bacterial illness (SBI) must be considered in the undervaccinated or unvaccinated child.
- Viruses cause the vast majority of childhood febrile illnesses and are generally self-limited and benign.
- SBI is growth of pathogenic bacteria in a previously sterile site, such as urinary tract infection (UTI), bacteremia, meningitis, osteomyelitis, bacterial gastroenteritis, bacterial pneumonia, cellulitis, or septic arthritis.
- The rate of SBI in infants younger than 3 months old presenting with fever is between 6% to 10%.
- Infants 28 days old and younger are at much higher risk for bacterial illness with fever because of their immature immune systems and incomplete vaccination status, making aggressive evaluation of these children important.
- Empirical treatment of febrile neonates is indicated and appropriate antibiotic regimens include ampicillin plus either gentamicin or cefotaxime, which cover the bacterial organisms likely in this age group.
- Empirical treatment for herpes simplex virus (HSV) should be considered in any neonate with a maternal history of genital herpes, who appears ill, presents with fever and seizure, has cutaneous vesicles on physical examination, or evidence of transaminitis or coagulopathy.
- The most common cause of SBI in children continues to be UTI, and the only reliable method to obtain urine in a non–toilet-trained infant is bladder catheterization or suprapubic aspiration when a catheter sample cannot be obtained.
- Bacterial meningitis can occur at any age but most commonly presents in a relatively small proportion of febrile infants younger than 3 months old (3/1000).
- Respiratory syncytial virus (RSV) and influenza are common viral causes of fever and respiratory distress in infants, although the presence of viral infection does not lower the risk of concomitant SBI in children younger than 28 days old.
- In older infants and children, the documented presence of RSV or influenza significantly reduces the incidence of SBI and can be used to modify the evaluation. Because UTI is still common in this population, a urinalysis should be obtained.

Key Concepts

- There are several risk-stratification strategies (ie, Boston, Rochester, and Philadelphia criteria) reported in the literature that have similar performance characteristics. All involve a laboratory evaluation designed to identify a subset of febrile infants younger than 3 months old that can safely be managed as outpatients with or without antibiotics.
- Standardization and adoption of a clinical practice guideline for the evaluation of the febrile infant has been shown to reduce variation and cost.
- Due to universal vaccination against pneumococcus, the evaluation of highly febrile children 3 to 36 months old has evolved from one of universal screening for occult bacteremia to one where clinical gestalt determines the need for bloodwork.
- Inflammatory markers, such as C-reactive protein (CRP) and procalcitonin, have been shown to predict bacterial illness in febrile children more accurately than the white blood cell (WBC) count but cannot be relied upon solely to rule-out SBI.
- Traumatic lumbar punctures occur relatively commonly in young infants and can make interpretation of cell counts difficult and use of various formulas to account for the protein and WBCs in the cerebrospinal fluid (CSF) after a traumatic tap should be used with caution.
- The risk of meningitis is exceedingly low in well-appearing children after a simple febrile seizure and lumbar puncture is not recommended.
- Children presenting with fever and petechiae are at risk for infection with meningococcus; blood should be obtained for complete blood count (CBC) and culture and if available CRP or procalcitonin. Children with abnormal CRP or elevated or depressed WBC count, or with bandemia should be treated with parenteral antibiotics and admitted. Lower risk, well-appearing children with normal laboratory parameters can be considered for close outpatient follow-up.
- Children with fever who also are receiving cytotoxic chemotherapy for cancer are at high risk for bacteremia and sepsis and should receive prompt broad spectrum antibiotic therapy after appropriate diagnostic evaluation (at the minimum, a CBC and blood culture).
- Patients with fever and a history of sickle cell disease are at risk for bacteremia from encapsulated organisms due to functional asplenia and should be considered high risk and should be admitted and treated.
REFERENCES

CHAPTER 166: QUESTIONS & ANSWERS

166.1. Which of the following are appropriate methods to obtain urine as part of a fever evaluation in a non-toilet-trained child?
A. Catheterized specimen
B. Clean catch, midstream
C. Suprapubic aspiration
D. A and B
Answer: D. The only reliable method to obtain urine in a non-toilet-trained child is bladder catheterization or suprapubic aspiration if a catheter specimen cannot otherwise be obtained. Bag collection has a high rate of false-positive results and should not be used in a child who is not toilet trained.

166.2. Which of the following statements regarding occult bacteremia in children younger than 36 months old is true?
A. Children with no obvious source of fever and a temperature higher than 102.2°F (39°C) have an incidence of bacteremia of 5%.
B. Most patients appear toxic.
C. The most common pathogen is Neisseria meningitidis.
D. There has been a marked decrease in the incidence of occult bacteremia since the advent of universal vaccination against pneumococcus and Haemophilus influenzae type B.
E. With pneumococcal bacteremia, most patients remain febrile until antibiotic therapy is initiated.
Answer: D. Children younger than 36 months old with fever higher than 102.2°F (39°C) and no obvious source have an incidence of occult bacteremia of less than 1%. Most patients appear nontoxic. The most common pathogen in positive cultures is *Streptococcus pneumoniae*, and the incidence of infection has dropped dramatically since the advent of universal vaccination. With pneumococcal bacteremia, most patients become afebrile in 3 or 4 days with or without antibiotic therapy.

166.3. A 3-year-old boy presents with fever of 103°F. His mother reports that the fever started approximately 5 days ago, and he has an associated maculopapular rash. On examination, you find the patient also has bilateral conjunctival injection, a strawberry tongue, and swelling of his hands and feet. Which of the following medications should be included in the treatment of this patient?
A. Aspirin
B. Clindamycin
C. Decadron
D. Penicillin G
E. Rocephin

Answer: A. This patient has Kawasaki disease. Treatment includes amelioration of symptoms and prevention of coronary aneurysms, which are normally treated with aspirin and immunoglobulin. There are no indications for antibiotics or steroids.

166.4. A 2-year-old presents with a high fever and vomiting. On examination, you find an irritable child with a rectal temperature of 102°F rectal and a stiff neck. The patient’s past medical history is significant for hydrocephalus with a ventriculoperitoneal shunt placement. You suspect the patient has a ventriculoperitoneal shunt infection. Which of the following is the most likely bacterial pathogen?
A. *Haemophilus influenzae*
B. *Neisseria meningitidis*
C. *Staphylococcus aureus*
D. *Staphylococcus epidermidis*
E. *Streptococcus pneumoniae*

Answer: D. Patients with ventriculoperitoneal shunts and fever must be evaluated for shunt infection. The most common bacterial pathogen is *S. epidermidis*. 
Pediatric Respiratory Emergencies: Upper Airway Obstruction and Infections

Emily Rose

CHAPTER 167

PRINCIPLES

Respiratory distress from upper airway obstruction is a rare but potentially catastrophic emergency in young children. Causes include acute infectious processes, congenital anomalies, or a foreign body in the airway or esophagus. Children are predisposed to respiratory failure due to increased airway resistance (small, compressible airway), low functional residual capacity, high oxygen metabolism, which leads to quicker fatigue, and shorter safe apnea time, with precipitous hypoxia.

Clinical presentations of children with upper airway disease vary with cause, predisposing factors, and age at presentation:
- Acute infections of the upper airway range from relatively mild distress and self-limited signs to symptoms to the abrupt onset of a rapidly progressive airway obstruction.
- Undiagnosed congenital anomalies of the airway and surrounding structures may be manifested as chronic or progressive stridor or simply difficulty with feeding.
- An infant with a congenital airway anomaly in whom an acute airway infection develops is at higher risk for decompensation and respiratory failure.
- Upper airway obstruction from a foreign body in the airway or esophagus can cause partial or complete airway obstruction and may require urgent, advanced, airway management skills.

CLINICAL FEATURES

Recent history and observation of the child typically provide clues to the cause of the airway obstruction. Important items to elucidate in the history include the following:
- Onset and duration (acute vs. chronic)
- Associated symptoms (e.g., respiratory distress, fever, toxicity, drooling, cyanosis, neck stiffness or torticollis)
- Progression with age (number of bouts and severity of “croup” with increasing age)
- Exacerbating factors (supine vs. prone position, upper respiratory infection [URI], crying)
- Feeding abnormality or dysphagia
- Prior airway procedures, such as intubation in the neonatal period
- Choking episode indicating possible foreign body aspiration
- Baseline noises, quality of cry and voice to assist the emergency clinician in pinpointing the location of obstructive lesion

Observation and physical examination should include vital signs (respiratory rate, heart rate, oxygen saturation) and indicators of increased work of breathing (retractions, flaring, grunting, stridor, wheezing) to gauge severity of the distress. Observe the character and timing of stridor and symmetry and quality of breath sounds. Respiratory failure is identified by the presence of extreme distress, hypoventilation or hyperventilation, altered mental status, pale, mottled or cyanotic skin color, and/or hypotonia. Stridor may not be present in respiratory failure due to lack of airflow.

Stridor (from the Latin, *stridulus*, indicating creaking, whistling, or grating) is the classic sound associated with upper airway obstruction. Stridor is a harsh vibratory sound of variable pitch caused by partial airway obstruction or collapse and the resultant turbulent airflow through some portion of the airway, from the nose to the trachea. Stridor is described by timing in the respiratory cycle (inspiratory, expiratory, biphasic) and quality (coarse or high-pitched; Table 167.1). Inspiratory stridor is usually associated with obstruction above the glottis, expiratory stridor with intrathoracic obstruction, and biphasic stridor typically with a critical or fixed obstruction at any level. Stridor character differs by cause and anatomic location (Fig. 167.1).

Snoring or stertor is low-pitched inspiratory noise caused by nasal or nasopharyngeal obstruction. Stertor and stridor can coexist. Stridor from the pharynx, such as from a peritonsillar abscess, tends to have a sonorous, gurgling, and coarse quality. The voice may be altered and have a muffled or “hot potato” quality to it. High-pitched inspiratory stridor occurs in the supraglottic and immediate subglottic trachea, as in croup and laryngomalacia. The voice may sound hoarse or weak but a normal voice may be heard, even with a laryngeal cause of stridor.

Biphasic stridor is heard with inspiration and expiration and usually suggests a fixed lesion. Examples include laryngeal webs and vocal cord paralysis. Stridor from the lower part of the trachea is usually expiratory such as in bacterial tracheitis or aspirated foreign bodies (Fig. 167.2).

DIAGNOSTIC CONSIDERATIONS

Diagnostic Testing and Management

Definitive airway management takes precedence in an acute airway emergency. In a stable patient with an uncertain diagnosis, an individualized diagnostic evaluation is undertaken. Lateral and anteroposterior radiographs of the soft tissues of the neck may be helpful to assess the adenoid and tonsillar size, contour of the epiglottis, thickness of the retropharyngeal soft tissue space, vallecula, aryepiglottic folds, and tracheal air column (Fig. 167.3). The child’s head should be positioned in extension and film taken during inspiration. Chest views assess the heart size, trachea and bronchi, location of the aortic arch, and presence of other pulmonary pathologic processes.

Additional studies may be indicated in specific settings. Bedside fiberoptic nasopharyngoscopy allows for the visualization and assessment of the supraglottic structures and vocal cords. Fiberoptic-assisted intubation may occur through the nasopharyngoscope. Esophagography can define lesions compressing the airway and trachea; computed tomography (CT), magnetic resonance imaging (MRI), and/or bronchoscopy may be needed to evaluate the upper airway.

**Differential Diagnoses**

**Supraglottic Airway Diseases**

The supraglottic portion of the airway includes the nose, pharynx, epiglottis, and surrounding structures. Diseases of the nose and pharynx are commonly associated with noisy congested breathing and respiratory distress. Congenital lesions involving these structures may cause mild symptoms at baseline but dramatic distress when there is a superimposed infectious process. Congenital lesions include choanal atresia, macroGLOSSIA, micrognathia, thyroglossal duct cyst, and lingual thyroid. Acquired causes of supraglottic disease include a nasal foreign body, nasal polyps, hypertrophic tonsils and adenoids, epiglottitis, retropharyngeal...
Retropharyngeal infections typically pro-\textit{stridor}.

- Expiratory
  - Tracheal
  - Bronchial

and congenital hypothyroidism. The increased secretions with a URI exacerbate underlying obstruction and may induce stridor or labored breathing. Good head positioning with nasal suctioning should be performed to relieve the obstruction.

**Micrognathia.** With micrognathia, an abnormally small mandible posteriorly displaces the normal-sized tongue (eg, Pierre-Robin and Treacher-Collins syndromes). Obstructive symptoms typically worsen when supine.

**Retropharyngeal Abscess**

A retropharyngeal abscess is a potentially life-threatening airway emergency resulting from infection of the retropharyngeal soft tissue space. The retropharyngeal space is a potential space between the posterior pharyngeal wall and prevertebral fascia that extends from the base of the skull to the level of T2. It is rich in lymph tissue that drains the nose, pharynx, sinuses, and ears. An abscess may result from direct trauma from a fall with an object in the mouth such as a toothbrush, suppuration of lymph nodes, contiguous spread of infection, or hematogenous seeding. It is usually a disease of infants and toddlers because the lymphatic chains are prominent in the young and atrophy before puberty. Approximately 50% of pediatric cases occur in children 6 to 12 months of age, most occur before 3 years of age, and 96% of all diagnosed pediatric retropharyngeal abscesses are seen before 6 years of age. These infections are commonly polymicrobial, with \textit{Streptococcus} and anaerobes the most commonly isolated organisms. Consider methicillin-resistant \textit{Staphylococcus aureus} (MRSA) in severe infections such as jugular venous thrombosis or mediastinal extension.

**Clinical Features.** Retropharyngeal infections typically progress from cellulitis to organized phlegmon to mature abscess. Presenting symptoms may vary. Common signs and symptoms include fever, sore throat, neck stiffness or nuchal rigidity, torticol-

**Diagonal Testing.** Careful evaluation of airway patency takes precedence in the management of a child with a presumed retropharyngeal abscess. Examination of the pharynx may reveal bulging of the posterior pharyngeal wall. A soft tissue lateral view of the neck may be helpful to establish the diagnosis; in the normal patient, the width of the retropharyngeal space should not exceed the diameter of the adjacent vertebral body (Fig. 167.4). The soft tissue width should not be larger than 6 to 7 mm at C2, regardless of the patient’s age. At C6, this distance should not exceed 14 mm in children younger than 15 years and 22 mm in adults. Most patients will demonstrate retropharyngeal thickening on the lateral neck radiograph. An air-fluid level may be present in perforation or anaerobic infections. Redundant soft tissue of the retropharyngeal space complicates the interpretation of lateral neck films in young infants with a retropharyngeal abscess. Artificial widening of a normal retropharyngeal space is commonly seen when the radiograph is taken with the head and neck in flexion or during exhalation. CT scanning of the neck (thin cuts to T2) may be beneficial in delineating the size and extent of

![Fig. 167.3. Normal appearance of upper airway structures on a lateral neck radiographic study. Note the hyoid bone, epiglottis, retropharyngeal space, and tracheal air column.](image-url)

![Fig. 167.4. Retropharyngeal Abscess](image-url)
Mononucleosis

Infectious mononucleosis, caused by the Epstein-Barr virus (EBV), can lead to mucosal edema and an exudative pharyngitis. Uncommonly, massive tonsillar enlargement can occur and create upper airway distress. EBV IgM antibody is the preferred test for infective mononucleosis (>90% sensitive), particularly in children younger than 4 years who are less likely to generate heterophile antibodies with primary EBV infection. In older children and adults, the heterophile antibody is measurable in 50% of patients within the first week of illness and in 60% to 90% in weeks 2 and 3.

In addition to airway management and general supportive care, some studies have shown the benefit of steroids and racemic epinephrine in reducing tonsillar edema. Although steroids decrease pharyngitis symptoms, it is important to consider an underlying lymphoid malignancy. Evaluate a child for diffuse lymphadenopathy, hepatosplenomegaly, and rash. The absence of these on the physical examination and a normal complete blood count makes a lymphoid malignancy unlikely. Treatment with glucocorticoids prior to the diagnosis of leukemia may delay leukemia diagnosis, increase the risk of tumor lysis syndrome, complicate risk stratification, and ultimately result in fatal complications. Therefore, great caution should be exercised in using glucocorticoids in children and adolescents, and should be avoided in children younger than 14 years or in a child who has any signs of possible lymphoid malignancy.

Ludwig’s Angina

Ludwig’s angina is an aggressive, rapidly spreading, woody inflammation of the sublingual, submandibular, and submaxillary spaces, with potential for airway obstruction. Most patients have dental sources of infection, which are usually polymicrobial. The spread of infection is direct and not via the lymphatics, so involvement is typically bilateral and without associated lymphadenopathy. Enlargement and elevation of the tongue above the lower teeth, a tender woody induration in the sublingual space, trismus, and odynophagia are hallmark signs. Ludwig’s angina can create a functional upper airway obstruction or respiratory distress through significant swelling and direct airway compression. Subsequent abscess formation may occur. CT confirms the diagnosis—MRI may help delineate soft tissue involvement—and evaluates the extent of infection. Treatment involves broad-spectrum antibiotics with anaerobic coverage, airway support, and admission for close monitoring. Otolaryngology and anesthesia consultants may facilitate planning and support if an emergent airway is required.

Epiglottitis

Although still a feared pediatric emergency, acute epiglottitis has declined markedly in incidence since the widespread administration of Haemophilus influenzae type b vaccine in the 1980s.

Principles. Epiglottitis is an invasive bacterial disease that causes inflammation and edema of the epiglottis, aryepiglottic folds, arytenoids, and surrounding supraglottic tissues. As these structures become inflamed and distended, they protrude downward and over the glottic opening. Supraglottic swelling reduces the upper airway caliber and causes turbulent airflow during inspiration (stridor). The epiglottitis may also act as a ball valve, obstructing airflow during inspiration but permitting exhalation. This traditional profile of Haemophilus influenzae type b (Hib) in young children has changed; the overall incidence has decreased, and now epiglottitis is relatively more common in older children and adults. However, Hib is still the most common infectious
cause of epiglottitis in children and can occur in fully immunized children. Additional causes include other *H. influenzae* types (A, F, nontypeable), streptococci, and *Staphylococcus aureus* (including methicillin-resistant strains). Immunocompromised children may have other infections such as *Pseudomonas aeruginosa* and *Candida* spp. Noninfectious causes are rare and include thermal injury from swallowing of hot liquids, steam inhalation, caustic ingestions, allergic reactions, foreign body and irritant injuries, and lymphoproliferative disorders.

**Clinical Features.** Epiglottitis is classically acute in onset. It is marked by high fever, intense sore throat, toxicity, and rapid progression. Children with epiglottitis appear anxious and maintain a sniffing or tripod position, with the jaw jutting forward and the neck extended to maximize airway patency. As symptoms worsen, cough and phonation are usually absent. Drooling is prominent because of an inability to swallow. Toxicity, altered mental status, dyspnea, stridor, retractions, and fever are common initial symptoms; the diagnosis is often delayed and is associated with a significantly increased mortality rate. Croup is a common misdiagnosis made in young children and those without prominent drooling and difficulty swallowing. The older patient is less likely to show dramatic signs of upper airway obstruction compared with the younger child because the diameter of the airway is larger and thus takes a greater degree of swelling to produce symptoms. These patients often complain of a sore throat that is out of proportion to physical findings and may also exhibit tenderness on palpation of the anterior neck. Epiglottitis caused by bacteria other than *H. influenzae* tends to have a slower onset and is less likely to cause airway compromise.

**Diagnostic Strategies.** When epiglottitis is strongly suspected, a lateral neck radiograph can be helpful to confirm the diagnosis and should be evaluated for an enlarged epiglottis (thumbprint sign; Fig. 167.5), thickened aryepiglottic folds, lack of air in the vallecula, and dilated hypopharynx. However, up to 70% of all patients with epiglottitis have normal radiographic findings. Careful observation of a child in consultation with an otolaryngologist is essential, and clinicians skilled in airway management should accompany the patient at all times.

**Management.** For the younger child, the importance of securing the airway takes precedence over diagnostic evaluation. A stable patient who is maintaining a patent airway and adequate oxygenation should not be moved or repositioned for examination, laboratory tests, or radiography. Such patients should be carefully transported to a setting where definitive airway management can be achieved in a controlled fashion, generally the operating room. Adolescents with epiglottitis generally have signs and symptoms of adults and do not often require airway stabilization. These patients can be managed as inpatients in a pediatric intensive care unit (PICU) setting with IV antibiotics but do not require immediate airway management unless signs and symptoms dictate that this is the case.

Unstable patients with respiratory failure require assisted ventilation. Bag-mask ventilation should be attempted first and, if successful, continued until intubation can be performed. If neither bag-mask ventilation nor intubation is successful, more aggressive techniques, such as needle cricotomypodotomy or tracheotomy, may be indicated. Regardless of the approach to securing the airway, it is prudent for the emergency clinician to consult other experts in airway management rapidly, such as an anesthesiologist (fiberoptic intubation), otolaryngologist, or general surgeon (surgical approaches), so that a plan of approach can be made and morbidity minimized. Patients often remain intubated for 3 to 5 days in order for antibiotic therapy to reduce inflammation and surrounding tissue edema. A second- or third-generation cephalosporin is recommended.

**Trauma and Burns**

Thermal injury from facial burns and inhaled smoke or steam and trauma to the face and neck can create physical findings similar to those of infectious epiglottitis. Rapidly progressive stridor, drooling, an unwillingness to lie flat, and a swollen inflamed epiglottis may occur. Aspiration of hot liquids is the most common cause of airway burns in infants and young children. Toddlers are particularly prone to inhalation of hot liquids because they can eat and drink independently without initially being attentive to temperature. The initial physical examination of the oropharynx may be relatively normal. Health care providers should electively secure the airway when laryngeal edema and progression of symptoms and edema are suspected. Bronchodilators may help with bronchospasm; steroids are not routinely recommended.

**Allergic Reactions**

Acute allergic reactions may cause supraglottic edema with respiratory distress and stridor. Food is the most common precipitant in infants and children. Children with peanut allergies and those with atopy and asthma have a higher mortality rate. The treatment of anaphylaxis is epinephrine. Intramuscular epinephrine (1 mg/mL solution) at 0.01 mg/kg up to 0.5 mg per dose is initial management and may be repeated twice. IV epinephrine (0.1 mg/mL solution) at a 0.01 mg/kg bolus followed by 0.1–1 mcg/kg/min up to 10 mcg/min may be necessary for patients in shock with anaphylaxis. IV fluids and oxygen should be administered. Nebulized epinephrine may be given to reduce airway edema and other bronchodilators may be given for epinephrine-resistant bronchospasm. H1 and H2 antihistamines and steroids are commonly given for symptomatic relief but do not aid in acute airway obstruction. Intubation may be required and should be considered early. On discharge from the hospital, all patients with anaphylaxis should be given a prescription for an epinephrine autoinjector (0.15 mg for children <30 kg; 0.3 mg for older children) and instructed in its use. Follow-up with the primary care physician for allergist referral and a medical alert bracelet may also be recommended.
Diseases of the Larynx

The larynx and vocal cords are commonly involved with obstructing airway disease. Many obstructing conditions are congenital lesions, including laryngomalacia, laryngeal web, and vocal cord paralysis. Acquired lesions include laryngeal papillomas.

**Congenital Lesions.** Laryngomalacia is the most common cause of chronic stridor in infants and accounts for 60% to 75% of congenital laryngeal anomalies. It is a result of incomplete development of the supporting cartilage of the larynx. With inspiration, the long floppy epiglottis, arytenoids, and aryepiglottic folds are drawn into the larynx and create a partial obstruction (Fig. 167.6). Baseline inspiratory stridor begins several weeks after birth and worsens with supine positioning, neck flexion, and increased respiratory effort (crying, URI). Laryngomalacia is rarely associated with significant respiratory distress, feeding difficulties, or failure to thrive. Most patients experience complete resolution of symptoms by 2 years of age and are treated conservatively. Fiberoptic bronchoscopy is used to confirm the diagnosis and identify the existence of coexisting or synchronous anomalies (eg, subglottic stenosis, tracheomalacia). Surgical intervention is warranted in severe cases in which the child suffers from apneic events, respiratory compromise, pulmonary hypertension, or failure to thrive.

Vocal cord paralysis is the second most common cause of chronic stridor in infants. Bilateral vocal cord paralysis results in severe respiratory distress and stridor and typically requires intervention for airway protection. It is often associated with serious central nervous system abnormalities, such as Arnold-Chiari malformations. Unilateral vocal cord paralysis is usually left-sided and related to traction on the left recurrent laryngeal nerve at birth or compression from mediastinal structures. Infants with unilateral vocal cord paralysis have a hoarse weak cry, feeding difficulties, and aspiration. Stridor often worsens with distress and improves with positioning the affected side down.

A laryngeal web results from failure of complete canalization of the airway. Most webs lie between the cords and appear as a partial anterior fusion (Fig. 167.7). The spectrum of symptoms reflects the size of the web. Small webs may cause a hoarse weak cry and mild stridor. Larger, more complete webs are associated with aphonia and severe respiratory distress.

**Acquired Lesions**

**Laryngeal Papillomas.** Laryngeal papillomas are the most common benign laryngeal neoplasm in children and the second
Croup (laryngotracheobronchitis) is the most common infectious cause of upper airway distress and obstruction in childhood. It accounts for more than 90% of all cases of stridor in children. It usually occurs between 6 and 36 months of age but can be seen from early infancy through school age. Parainfluenza virus accounts for 50% to 75% of cases; respiratory syncytial virus, influenza A and B viruses, and rhinovirus cause the remainder. The clinical picture of croup associated with influenza is more severe than with parainfluenza. Croup is caused by inflammation, edema, and edema of the loosely adherent mucosal and submucosal tissues of the subglottic space. The inflamed mucosa expands into the airway lumen because the cricoid cartilage forms a complete cartilaginous (nonexpanding) ring in this part of the trachea.

**Viral Croup**

**Principles of Disease.** Croup (laryngotracheobronchitis) is the most common infectious cause of upper airway distress and obstruction in childhood. It accounts for more than 90% of all cases of stridor in children. It usually occurs between 6 and 36 months of age but can be seen from early infancy through school age. Parainfluenza virus accounts for 50% to 75% of cases; respiratory syncytial virus, influenza A and B viruses, and rhinovirus cause the remainder. The clinical picture of croup associated with influenza is more severe than with parainfluenza. Croup is caused by inflammation, edema, and edema of the loosely adherent mucosal and submucosal tissues of the subglottic space. The inflamed mucosa expands into the airway lumen because the cricoid cartilage forms a complete cartilaginous (nonexpanding) ring in this part of the trachea.

**Clinical Features.** Croup is diagnosed clinically. A 1- to 3-day prodrome of mild fever and URI symptoms is followed by a fairly abrupt onset of barking cough, hoarse voice, and high-pitched inspiratory stridor. Croup symptoms typically resolve in 4 to 7 days. A subset of children with croup has involvement of the lower airway and exhibit bronchoconstriction, lower airway edema, and atelectasis. A simplified clinical approach to the differential diagnosis for croup is shown in Fig. 167.10. Scoring systems have been developed for the assessment of croup; these include an evaluation of worsening stridor, retractions, cyanosis, heart rate, and respiratory rate. Although a formal croup score is often not assigned in many clinical settings, the determination of mild, moderate, or severe croup should be based on careful evaluation of these five signs as well as on mental status and air movement (Fig. 167.11).

Mild croup is characterized by an intermittent barking cough, stridor with agitation but not at rest, mild tachypnea, and tachycardia. A child with mild croup is minimally distressed and well hydrated and has normal mental status. Moderate croup is characterized by audible stridor at rest, worsening stridor with agitation, barking cough, and increased work of breathing (retractions, tachypnea, tachycardia). A patient with moderate croup may be fussy but is alert, interactive, and comforted by parents. Hypoxia is atypical in mild or moderate croup. When hypoxia is seen, it may signify concomitant lower respiratory disease, another disease process, or severe croup. Mild croup occurs in 85% of children; fewer than 1% of children have severe croup. Laboratory tests are nondiagnostic, and radiographic studies of the neck do not change management nor are they sensitive or specific. The classic x-ray finding is a steeple sign—a tapered narrowing of the normal shouldered appearance of the subglottic trachea—which can be seen in those with croup and also in patients without the disease.

**Management.** Glucocorticoids reduce symptoms, decrease the need for aerosolized epinephrine, result in fewer readmissions to the ED, and shorter ED and hospital stays. Oral dexamethasone in a dose as small as 0.15 mg/kg is as effective as higher doses in decreasing the duration of symptoms and hospitalization. Inhaled budesonide (2 mg/dose) is as effective as oral dexamethasone (0.6 mg/kg) in decreasing the duration of hospital stay, improving clinical symptoms, and decreasing the ongoing requirement for aerosolized epinephrine.

Aerosolized epinephrine, which reverses edema and relieves acute symptoms through vasoconstriction in the subglottic...
The initial emergency assessment must be performed to ensure that stridor and respiratory distress do not recur.20 Stridor at rest or only when agitated in children with croup should be given to children with stridor at rest. It is a temporizing measure with a quick onset of action (<10 minutes) and duration of 1 to 2 hours. The l form of epinephrine is the active isomer and has the same degree of safety and efficacy as racemic epinephrine; either form may be used.20 Patients should be observed in the ED for 2 to 3 hours after epinephrine administration to ensure that stridor and respiratory distress do not recur.20

There is some evidence to suggest short-term benefit of heliox inhalation in moderate to severe croup; however, I cannot recommend its routine use.21 Cool mist has not been demonstrated to improve outcomes but there is insufficient evidence to support its routine use.11,12,14,22

Most children with croup can be safely discharged, provided respiratory distress and stridor have resolved. A small percentage of patients with croup require admission. Several factors may impact the decision to admit a child with moderate croup, such as severity of symptoms at initial evaluation, persistence of respiratory distress, stridor at rest, hypoxia, poor response to treatment, dehydration, history suggesting airway disease or recurrent croup, young age (<6 months), high fever, and poor social support (Box 167.1).

Severe croup is rare (<1%) and associated with signs of impending airway obstruction and respiratory failure—fatigue, hypoxia, hypercapnia, abnormal mental status, and extreme respiratory distress. In the rare case in which intubation is required, an endotracheal tube at least a half-size smaller than expected for the child’s size is often necessary. If the endotracheal tube that can be passed is too small to allow adequate ventilation, tracheostomy may be required.

### Spasmodic or Atypical Croup
Spasmodic or atypical croup is a somewhat indistinct clinical entity with many features that overlap those of viral croup. There is no consensus on the definition but the term atypical croup is often used to describe numerous recurrent episodes or croup in children outside the expected age group. An association with allergy, atopy, airway hyperreactivity, asthma, and gastro-esophageal reflux has been described. Large airway lesions (usually subglottic stenosis) may be present and contribute to the pathophysiology.23

### Diseases of the Trachea
Obstruction of the trachea distal to the subglottic space can be a result of congenital and acquired lesions.

**Congenital Lesions.** Tracheomalacia results from abnormally soft, undeveloped supporting cartilage of the tracheal rings. Primary or congenital tracheomalacia is seen in otherwise healthy term newborns, as well as in infants with conditions such as Down syndrome and DiGeorge syndrome. Healthy infants with isolated disease have a good prognosis because symptoms improve as the
cartilage strengthens with growth. Secondary disease is associated with extrinsic compression of the trachea (eg, vascular rings, tumor, nodes, cysts). Tracheomalacia should be suspected in patients with a history of stridor that increases during the first few weeks of life and worsens with agitation, supine positioning, and infection. Plain radiographs are usually nondiagnostic but dynamic studies, such as fluoroscopy, may be helpful. Referral to the patient’s primary care physician for further evaluation after ED care should be done.

Tracheal stenosis is a congenital anomaly that results from complete tracheal rings. Infants have persistent stridor and respiratory distress. Because the tracheal diameter is fixed, symptoms worsen with agitation and age.

Tracheal compression may occur externally from vascular anomalies or mediastinal lesions (Fig. 167.12). A vascular ring is an anomaly of the aortic arch and related vessels in which a ring of vessels encircles the trachea, esophagus, or both. Examples of vascular rings include a double aortic arch, right aortic arch with a persistent left ligamentum arteriosum, anomalous innominate artery and anomalous left common carotid artery, left pulmonary artery, or aberrant right subclavian artery. Stridor, wheezing, dyspnea, and cough are common initial symptoms and are frequently mistaken as a URI. Many patients with vascular rings have additional cardiovascular anomalies. The association of congenital cardiac anomalies is a consideration in the evaluation of these patients. Other associated mediastinal lesions that can compress the trachea include esophageal duplication cyst, bronchogenic cysts, mediastinal cyst, teratoma, lymphoma, and lymphadenopathy.

Infants with vascular rings typically present with persistent, unexplained respiratory and feeding problems. A chest radiograph revealing an abnormal (right-sided) aortic arch may suggest the diagnosis in the ED; barium esophagography has traditionally been considered to be the single most important diagnostic procedure in patients with complete vascular rings (Fig. 167.13). The need for additional studies, such as CT, MRI, angiography, or bronchoscopy, should be individualized.

**Bacterial Tracheitis**

**Principles.** Bacterial tracheitis—membranous croup, bacterial croup, pseudomembranous croup—is a serious cause of stridor and airway obstruction in children. The epidemiology of upper airway infections has changed since widespread immunization for *H. influenzae* and the use of steroids for croup. This has increased the relative frequency of bacterial tracheitis as a cause of respiratory failure from upper airway infection. Bacterial tracheitis is three times more likely to cause respiratory failure than epiglottitis and viral croup combined. Bacterial tracheitis usually affects younger children, but may occur at any age.

The pathogenesis of bacterial tracheitis is severe inflammation of the tracheal epithelium and production of thick mucopurulent secretions. The lining of the trachea forms a loosely adherent membrane that may become necrotic and slough, occluding the lumen. Microabscesses may be present in the tracheal mucosa. Perforation and pneumomediastinum have been described. Traditionally, *S. aureus* (including MRSA) has been the organism primarily responsible for bacterial tracheitis but many causative bacteria have been reported. Fungal tracheitis in immunocompromised individuals portends a grave prognosis.

**Clinical Features.** The classic presentation of bacterial tracheitis is a toxic child with high fevers and rapidly worsening stridor that fails to improve with racemic epinephrine. Symptoms may overlap with those of croup and epiglottitis (Table 167.2). Most patients experience a viral prodrome of fever, barking cough, and stridor. These symptoms typically intensify as the bacterial superinfection grows on damaged tracheal epithelium. The child appears toxic, and signs of airway obstruction and respiratory failure may develop acutely. Less commonly, primary bacterial tracheitis may occur with a fulminant onset and rapid progression to acute respiratory distress. Features that suggest bacterial tracheitis include a viral prodrome followed by acute decompensation, symptoms atypical for croup (eg, high fever, cyanosis, severe distress), poor response to usual treatment of croup (eg, steroids, aerosolized epinephrine), and inspiratory and expiratory stridor. Changes in bacteriologic profiles have produced less virulent but more prolonged infections, increasing the diagnostic challenge.6

**Diagnostic Strategies.** The evaluation of a toxic-appearing child with bacterial tracheitis should be conducted expeditiously. Laboratory tests are nondiagnostic. The white blood cell count is often normal or slightly elevated, and blood cultures are rarely positive in bacterial tracheitis. Lateral and anteroposterior views of the neck and chest may be helpful. Findings on plain radiographs include subglottic narrowing, a ragged edge of the usually smooth tracheal air column, and a hazy density within the tracheal lumen, mimicking the appearance of airway foreign bodies. The epiglottis and supraglottic structures appear normal. In addition, the chest radiograph may reveal coexisting pneumonia. Bronchoscopy is diagnostic and therapeutic and should be performed emergently (Fig. 167.14). This procedure should allow visualization of the supraglottic structures and larynx, exclusion of other disease, suctioning of tracheal secretions and debris, and establishment of an artificial airway.

**Management.** Severe distress may rarely require immediate intubation and suctioning in the ED, although airway management in the operating room is preferred. Endoscopic tracheal débridement may result in significant clinical improvement and allow the child to be managed without intubation. Serial endoscopy may be needed to manage secretions. Endotracheal intubation is required in children with respiratory distress and hypoxia. Patients should be admitted and receive supplemental oxygen, fluid resuscitation, and broad-spectrum antibiotics.

Broad antibiotic coverage is recommended with an antistaphylococcal agent (eg, vancomycin, clindamycin) plus a third-generation cephalosporin (eg, cefotaxime, ceftriaxone). Alternatively, an antistaphylococcal agent plus ampicillin-sulbactam may be used. In penicillin-allergic patients, vancomycin or clindamycin plus a quinolone should be administered (ciprofloxacin if *Pseudomonas* is a concern or levofloxacin if *Streptococcus pneumoniae* is suspected). Although 7 to 10 days is usually sufficient, longer courses of antibiotics may be necessary for children with extratracheal infection of persistent tracheal inflammation. Complications of bacterial tracheitis include toxic shock syndrome, septic shock, renal failure, postintubation pulmonary edema, acute respiratory distress syndrome, and need for reintubation. Residual subglottic stenosis has been described.

**Foreign Bodies**

**Airway Foreign Body**

**Perspective.** Asphyxia from airway obstruction by an airway or esophageal foreign body is a common cause of death in children. Round foods (eg, peanuts, grapes, raisins, hot dogs) are especially common. Conformable objects are the most difficult to
manage and remove, and balloons, including those made from examination gloves found in physicians’ offices, are the objects most likely to result in death.

Large objects that lodge in the upper airway and trachea cause dramatic signs of upper airway obstruction (eg, dyspnea, drooling, stridor, cyanosis) and carry the worst prognosis. Objects that pass through the subglottic space typically will lodge in a bronchus, usually the right mainstem bronchus, or in a more terminal part of the airway.

**Clinical Features.** An upper airway foreign body can cause partial or complete obstruction. Clinical signs of complete obstruction include poor air exchange, ineffective cough, severe distress, and cyanosis. Foreign body aspiration that has settled in the lower airways may have subacute symptoms such as unilateral wheeze or may present later (days to years) as recurrent pneumonia. The sensitivity of a witnessed choking episode varies in the literature.

**Diagnostic Testing.** In a child with an aspirated foreign body in the upper airway, there is often no time, nor is it prudent, to perform diagnostic imaging. In a stable patient, a portable lateral neck radiograph and chest radiograph may be obtained as long as the patient is allowed to maintain a position of comfort. Radiographic findings suspicious for foreign body aspiration include radiopaque materials, mediastinal shift, emphysema, and atelectasis. A normal chest radiograph cannot rule out a nonradiopaque foreign body. CT scan and virtual bronchoscopy (a reformatted three-dimensional CT image that generates intraluminal views of the airway to the sixth- and seventh-generation bronchi) may be used to aid diagnosis in equivocal cases. Diagnostic flexible bronchoscopy is indicated with significant clinical suspicion of foreign body aspiration, despite normal imaging.

**Management.** An acute obstructing upper airway foreign body requires emergent intervention with basic life support maneuvers. Choking infants younger than 1 year should be given five back blows delivered between the shoulder blades, followed by five chest thrusts with the head held below the trunk. Abdominal thrusts should not be performed in infants and may injure abdominal organs. Blind finger sweeps are no longer recommended and may push the object further into the airway. The Heimlich maneuver is used in conscious children younger than 1 year; chest compressions should be delivered to unconscious children. If there is no chest rise with assisted ventilation with a bag-mask device, advanced airway techniques are indicated. Laryngoscopy should be performed to attempt visualization and foreign body removal with pediatric Magill forceps. If the obstructing foreign body cannot be visualized, it may be pushed distally into the right mainstem bronchus with an endotracheal tube to ventilate the nonobstructed portion of the lung. Recruiting additional expertise from an otolaryngologist, anesthesiologist, or general surgeon may be valuable.

A patient who is adequately oxygenated and is moving air should be initially allowed to maintain a preferred position, continue coughing to clear the obstruction, and breathe spontaneously until operative management can be arranged. Paralysis with rapid sequence induction should be avoided if the patient is maintaining a patent airway; with paralysis, the airway tone may be lost, and a partial obstruction can become complete.

**Can’t Intubate, Can’t Ventilate Scenario.** Surgical cricothyrotomy is not recommended for infants and young children younger than 6 to 10 years. The anatomy changes with growth (ie, the larynx is high and cricothyroid membrane small), and it may be difficult to locate pertinent anatomy until a child is of school age. Tracheal compressibility also increases complication risk. Needle cricothyrotomy may also be used but significant CO2 retention limits its effectiveness.

Commercial percutaneous transtracheal ventilation kits may be purchased but homemade kits can be constructed using tools readily available in the ED. A 14- to 18-gauge angiocatheter (ETT) adaptor (or a 3.0-mm ETT connector directly to the anesthesiologist). These homemade kits are rigid and may easily become dislodged. Alternative setups include using IV tubing—attaching IV tubing to the anesthesiologist, cutting the tubing, and attaching a 2.5-mm ETT connector—or directly connecting oxygen tubing to the catheter with a Y connector or three-way stopcock. Bag-mask ventilation (recommended in children < 5 years) can be performed through the ETT adaptor at 10 to 12 breaths/min to minimize barotrauma by allowing for passive exhalation. Percutaneous transtracheal ventilation (in children ≥ 5 years) is given at an oxygen flow rate of 1 L/min/year of age with a 1:4 inspiration-to-expiration ratio (I:E). Adults should receive oxygen from the wall source at 15 L/min (50–58 psi) and children at a rate of 12 L/min (25–35 psi). Complete airway obstruction does not allow for passive exhalation and necessitates a reduction of bag-mask ventilation rate to five or six breaths/min or I:E ratio of 1:8 to 10 as a temporizing measure. Complications of needle cricothyrotomy include barotrauma and damage to adjacent structures.

---

**KEY CONCEPTS**

**Respiratory arrest** precedes most pediatric cardiac arrests. Quick recognition of an airway problem and intervention in potentially life-threatening upper airway obstruction in children are critical.

**Retropharyngeal Abscess**
- This is a potentially life-threatening emergency in young children with signs of upper airway obstruction or meningismus; a retropharyngeal abscess is often related to oral trauma.
- Retropharyngeal abscess is most frequently caused by *Staphylococcus aureus*, group A streptococci, and anaerobes. Treatment is admission, IV antibiotics and, for more severe cases, surgical drainage.

**Epiglottitis**
- Epiglottitis may be caused by many bacteria or local injury. In the post–*H. influenzae* type b vaccine era, the typical profile of epiglottitis has changed to include older patients.
- Clinical features of epiglottitis are often subtle, such as in the older adolescent, (eg, sore throat out of proportion to physical findings, anterior neck tenderness), but may also be dramatic, as in infants and young children (ie, drooling, stridor, toxicity, severe respiratory distress).

**Croup**
- Viral croup is the most common infection of the upper airway in young children.
- Glucocorticoids (usually given as a single oral dose of dexamethasone) reduces symptoms, hospitalizations, and length of stay in the ED.
- Treatment of moderate to severe croup includes vaporized epinephrine in addition to glucocorticoids. These patients can be discharged from the ED after a posttreatment observation period of 2 to 3 hours if they remain free of stridor and distress and have access to follow-up care.

---

*Continued*
Bacterial Tracheitis
- Suspect bacterial tracheitis when a URI progresses to acute toxicity and marked respiratory distress and stridor. Standard treatment for croup should be initiated but does not improve the patient’s symptoms. Antibiotic therapy should include a cephalosporin plus coverage for S. aureus, which is the most common cause of this infection.
- Bronchoscopy is diagnostic and therapeutic and should be emergently performed.

Airway Foreign Body
- Complete obstruction due to an airway foreign body requires emergent basic followed by advanced life support procedures for removal of the foreign body.
- Plain films may be negative in aspirated foreign bodies. Bronchoscopy should be performed with a clinical suspicion of aspiration.
- Emergency cricothyroidotomy may be required for obstructed patients who cannot be intubated or ventilated as a lifesaving temporizing measure; needle cricothyroidotomy is preferred for infants and young children because of the challenges in identifying landmarks and associated complications of surgical cricothyrotomy.

167.1. Which of the following is the most common cause of upper respiratory obstruction in childhood?  
A. Airway foreign body  
B. Bacterial tracheitis  
C. Croup  
D. Epiglottitis  
E. Retropharyngeal abscess

Answer: C. Although all the choices may lead to symptoms of airway obstruction in children, the most common cause of upper airway obstruction is viral croup.

167.2. A 3-year-old girl presents at 2 AM with complaints of a barking cough, which started abruptly overnight. Vital signs are heart rate, 140 beats/min, respiratory rate, 40 breaths/min, and temperature, 100.1°F (38°C). She has no history of asthma or wheezing. She appears to be in moderate distress and has audible stridor. Indications for admission include which of the following?  
A. Low-grade fever  
B. Prior history of croup  
C. Pretreatment for tachycardia and tachypnea  
D. Pretreatment for stridor  
E. Severe dehydration

Answer: E. Indications for admission of patients with croup include severe respiratory distress or failure, unusual symptoms (hypoxia and hyperpyrexia), anything but mild dehydration, persistence of stridor at rest after aerosolized epinephrine and steroids, persistence of tachycardia or tachypnea, and complex medical history (eg, prematurity, pulmonary or cardiac disease).

167.3. A 5-year-old immunized boy presents with stridor, low-grade fever, and nasal congestion. His family reports a barking-sounding cough. After initiating vaporized epinephrine, he appears well and is in no distress. The parents are requesting discharge. Which of the following would be the most appropriate next step in management?  
A. Administer dexamethasone (Decadron), observe the patient for 2 hours, and discharge if well.  
B. Admit the patient for overnight observation.  
C. Refer the patient for 2 hours, and discharge if well.  
D. Administer steroids.  
E. Observe the patient for 2 to 3 hours and then discharge if well.

Answer: A. The child has croup and, after being treated with vaporized epinephrine, should be observed for rebound stridor for a minimum of 2 hours. If the child is well, is in no respiratory distress, has a good hydration status, and is able to access emergency and follow-up care, he or she can then be safely discharged.

167.4. What is the ideal head position to assess a pediatric soft tissue radiograph of the neck for an upper airway pathology?  
A. Extension  
B. Extension during inspiration  
C. Flexion  
D. Flexion during inspiration  
E. Neutral

Answer: B. Gentle extension of the head gives the most accurate images, avoiding the artificial soft tissue widening that can be seen in flexion. Inspiration, if possible, allows maximal distention of the pharynx and the best viewing of soft tissue structures defined by an air–soft tissue interface.

167.5. Which of the following factors is least consistent with the diagnosis of peritonsillar abscess?  
A. Muffled, hot potato voice  
B. Pain radiating to the ear

REFERENCES

C. Patient 3 years of age
D. Patient 13 years old
E. Trismus

**Answer:** C. Peritonsillar abscess more commonly occurs in older children and teenagers, whereas retropharyngeal abscess is more common in a younger population. All the other signs or symptoms listed are consistent with peritonsillar abscess, along with deviation of the uvula away from the abscess side.

167.6. A 3-year-old immunized girl presents after a brief viral illness with progressive dyspnea, ill appearance, and high fever. The child is relatively still, appearing as if she is trying not to cough. Stridor is heard, and she does not respond to croup therapy. You notify the operating room, where the patient undergoes bronchoscopy, with suctioning and airway placement. Culture results are most likely to grow which of the following organisms?
A. *Bacteroides fragilis*
B. *Candida albicans*
C. Parainfluenza
D. *Staphylococcus aureus*
E. *Streptococcus pneumoniae*

**Answer:** D. The case described is consistent with bacterial tracheitis. Although *Candida*, parainfluenza, and *Streptococcus* have all been reported, *S. aureus* is most common. Broad-spectrum antibiotics are appropriate, with an emphasis on covering *S. aureus*. 

Asthma is the most prevalent chronic disease of childhood, affecting almost 7 million children in the United States. In the past 3 decades, childhood asthma prevalence rates have more than doubled. In addition, there are important racial disparities among children with this condition. Compared with white children, African American children have a 60% higher prevalence rate, 260% higher emergency department (ED) visit rate, 250% higher hospitalization rate, and 500% higher death rate due to asthma.

Anatomy and Physiology

Asthma is a lower airway disease marked by bronchoconstriction, mucosal edema, and pulmonary secretions. Upper respiratory infections (URIs) associated with copious rhinorrhea, a common trigger of an asthma exacerbation, may significantly increase airway resistance in young children. Because children have compliant chest walls and horizontally located ribs, their ability to use the thorax to increase tidal volume is limited; thus, ventilation is highly dependent on diaphragmatic movement. Also, minute ventilation is largely rate-dependent and may quickly lead to fatigue. An infant younger than 12 months has an oxygen consumption index that is double that of an adult. Increased airway resistance and a compliant chest wall predispose infants to tachypnea, increased work of breathing, and increased oxygen consumption. As a result, the infant with respiratory distress may rapidly develop hypoxemia, bradycardia, and cardiopulmonary arrest.

Clinical Features

All acutely wheezing children arriving for ED care should be attached to a cardiorespiratory monitor and have oxygen saturation determined by pulse oximetry. If needed, supplemental oxygen should be provided. After this, the emergency clinician may begin the clinical assessment.

History

To determine the initial degree of illness and initiate appropriate therapy quickly, a concise initial history should be obtained, followed by a physical examination that focuses on the cardiopulmonary systems. After therapy has begun, a more comprehensive history should include questions about asthma triggers, such as URIs, cigarette smoke, allergies, and exercise. Frequent ED visits or hospitalizations due to asthma may indicate poorly controlled asthma. The impact of asthma on the child’s life may be gauged by the monthly frequency of daytime or nighttime symptoms, including cough, as well as missed days of school or restricted activity. A child with persistent asthma marked by frequent symptoms should receive daily antiinflammatory therapy; those older than 5 years should monitor symptoms with a peak flow meter. Family and social histories should focus on asthma, cystic fibrosis, or atopic disease and on the adequacy of support systems at home.

Physical Examination

The initial focused examination includes assessing vital signs, mental status, and cardiopulmonary systems. A child who is anxious, restless, or lethargic may be hypoxemic. No single asthma score has been universally adopted to assess the degree of illness or treatment responses. However, most scores include some combination of respiratory rate, degree of wheezing, inspiratory-to-expiratory ratio, use of accessory muscles, and oxygen saturation. These scores can assist in the assessment of the pretreatment degree of illness and tracking the response to therapy.

Assessing the work of breathing should include a careful inspection of the chest and neck; palpation of the chest and neck may reveal subcutaneous air associated with a pneumomediastinum or pneumothorax. Severely ill children may have wheezing that is audible without a stethoscope or no wheezing due to poor aeration. Asymmetric wheezing suggests pneumonia, pneumothorax, or a foreign body. More anxiety-provoking parts of the examination, such as otoscopy, should be delayed until treatment is well underway.

Diagnostic Considerations

Differential Diagnoses

The differential diagnosis for childhood asthma includes bronchiolitis, laryngotracheobronchitis (croup), pneumonia, and gastroesophageal reflux (Table 168.1). Bronchiolitis is the disease that is most commonly confused with asthma, and the two cannot be distinguished by examination findings alone.

Croup may have a viral or allergic cause and affects children from infancy through early school age. Clinical presentation is marked by an abrupt onset of a harsh barking cough and inspiratory stridor. Symptoms are typically worse at night. Asthma will not be manifested with stridor alone, but a subset of children with croup may present with stridor and wheezing. Children with

Pneumonia may sometimes present with a component of wheezing, although rales and rhonchi are the usual auscultative findings. Infants and young children with pneumonia may also have high fever, cough, grunting, nasal flaring, retractions, and an asymmetric lung examination.

Diagnostic Testing

The oxygen saturation of any child with respiratory distress should be determined soon after ED arrival, and supplemental oxygen should be provided if the oxygen saturation is 92% or less. Most children with wheezing are presumptively treated for an asthma exacerbation without imaging or laboratory studies. Adjunctive studies, such as arterial oxygen saturation measured by pulse oximetry, may assist in determining the initial degree of illness. Performing an arterial blood gas (ABG) analysis is rarely indicated for children with asthma but may be obtained in children with severe bronchospasm and signs of respiratory failure despite initial therapy. A high or apparently normal partial pressure of carbon dioxide (PaCO₂ ≥ 40 mm Hg) in a child with hypoxia and retractions indicates impaired ventilation and impending respiratory failure.

Measurement of the peak expiratory flow rate (PEFR) is a means of obtaining an objective assessment of exacerbation severity. However, up to two-thirds of children older than 5 years are unable to complete PEFR testing during an asthma exacerbation. When feasible, the PEFR should be measured with the child standing and the best of three attempts recorded.

URIs marked by low-grade fever and coughing are common triggers of asthma exacerbations. These signs overlap with those found among children with pneumonia, making it difficult to determine the necessity of obtaining a chest x-ray. No set of predictors has been found that can accurately identify children likely to have radiographic abnormalities. ED physicians frequently obtain a chest x-ray for children in the ED with asthma but rarely are pneumonia or other unsuspected diagnoses discovered, even if the child has never wheezed before.

It should not be routine practice to obtain a chest x-ray for wheezing children, even for those who are febrile, wheezing for the first time, or requiring hospitalization. Performing chest radiography is indicated for those with a history of choking, focal chest findings, extreme distress, or subcutaneous emphysema. Reassessment after short-acting ß₂-agonist (SABA) treatment to evaluate for resolution of focal findings may further decrease the need to obtain a chest x-ray.

Management

Children can be stratified by degree of illness based on the physical examination (Fig. 168.1).

Mild Exacerbation

A mild exacerbation is characterized by alertness, slight tachypnea, expiratory wheezing only, mildly prolonged expiratory phase, minimal accessory muscle use, and oxygen saturation of greater than 95%. Patients with a mild exacerbation will usually only require SABA therapy. We agree with the Expert Panel of the National Heart, Lung, and Blood Institute (NHLBI), which recommends that patients receive therapy every 20 minutes in the first hour of care. Children with mild exacerbations often improve promptly with just one or two SABA treatments and many are managed without systemic corticosteroids (CS). However, CS may be given to mildly ill children who have received home SABA doses prior to presentation or to those who do not respond promptly to SABA therapy (see later, "Moderate Exacerbation").

Racemic albuterol has become the SABA of choice for treatment of children with acute asthma. Options for mode of delivery include a small-volume nebulizer (NEB) and metered-dose inhaler with a spacer (MDI-S). Most emergency clinicians use NEBs to administer SABA, regardless of illness severity, NEBs provide a passive means of receiving aerosolized medication because precise coordination between respiration and aerosol delivery is not needed; additionally anticholinergic medication and humidified oxygen may be delivered concurrently. However, delivery is inefficient, with only about 10% of the drug delivered to the small airways. Also administration takes about 10 minutes, increasing respiratory therapy time and costs.

On the other hand, spacers used with a MDI-S provide a reservoir of medication that is available to be inhaled. Therefore, precise coordination between actuation and inhalation is not needed, and there is no need for breath-holding. After each actuation, children should take five to eight breaths. Drug deposition in the oropharynx and systemic absorption are reduced with the use of a spacer, and decreased administration time may result in reduced costs. Face mask–equipped spacers are available for children too young to use the spacer’s mouthpiece, although mouthpieces are preferable for older children to decrease nasal filtering of the drug.

Numerous clinical trials and meta-analyses have consistently demonstrated that delivery by MDI-S is at least as effective as delivery by NEB. Among children 1 to 4 years old, MDI-S use was

| Levalbuterol | 1.25 mg of racemic albuterol in the ED treatment of more than 500 children with acute asthma. The use of levalbuterol was associated with a decreased need for hospitalization. Subsequently, three other randomized trials comparing the ED use of the two drugs failed to find a levalbuterol benefit. Another trial failed to demonstrate benefit with continuously nebulized levalbuterol. The cost of levalbuterol is more than 10 times that of racemic albuterol. Until there are more compelling data to demonstrate conclusively that the additional costs of levalbuterol are offset by clinical benefits, racemic albuterol is the drug of choice for children with acute asthma exacerbations.

**Fig. 168.1.** Emergency department management of acute asthma. **ED**, Emergency department; **IB**, ipratropium bromide; **ICS**, inhaled corticosteroids; **IM**, intramuscular; **MDI-S**, metered-dose inhaler with spacer; **NEB**, nebulizer; **PEFR**, peak expiratory flow rate; **PICU**, pediatric intensive care unit; **SABA**, short-acting β₂-agonist; **SQ**, subcutaneous.

**CHAPTER 168 Pediatric Respiratory Emergencies: Lower Airway Obstruction**
For those who are not already receiving inhaled corticosteroids, it is unclear if prescribing them at ED discharge leads to improved short-term outcomes. Among adult asthmatics discharged from the ED, the addition of inhaled flunisolide did not lead to improved outcomes. On the other hand, adults randomized to inhaled budesonide after ED discharge had a marked decrease in relapse rates, frequency of SABA use, and asthma symptoms. One review has concluded that there is "insufficient evidence that ICS [inhaled corticosteroids] therapy provides additional benefit" when added to systemic CS at ED discharge. Emergency clinicians rarely prescribe ICS at ED discharge, even to children who have persistent asthma. Rather than preventing ED relapse, ICS should be prescribed to help achieve long-term goals for patients with persistent disease. These patients have frequent symptoms—coughing or wheezing, frequent exacerbations requiring the use of SABA, or recurrent visits to the ED. ICS are safe and well tolerated at recommended doses and may be given concurrently with systemic CS. Longitudinal studies have shown that daily use of inhaled corticosteroids may decrease growth velocity, but these changes are small and reversible.

In addition to prescribing medications, emergency clinicians should also provide asthma education at discharge. Some EDs provide standardized information to families with a video or DVD while they undergo ED therapy. Descriptions of how to identify and avoid asthma triggers, written asthma action plan explaining proper steps to take in response to an asthma flare, review of discharge medications, and instruction on proper MDI-S use should be included. Follow-up asthma care within 1 to 4 weeks should be arranged.

### Moderate Exacerbation

A moderate exacerbation is characterized by alert tachyepnic children who have wheezing throughout expiration, an inspiratory-to-expiratory ratio of 1:2, and significant use of accessory muscles. Typically, the oxygen saturation will be 92% to 95% and the PEFR will be 41% to 70% of personal best. As with children experiencing milder attacks, the cornerstone of therapy is SABA therapy. Other medications include ipratropium bromide (IB) and CS.

IB, an anticholinergic agent, blocks reflex bronchoconstriction caused by stimulation of airway cholinergic receptors. It is available as an MDI and as a NEB solution for nebulization that may be mixed directly with albuterol. The use of a SABA with IB is more effective than an SABA alone. In a randomized controlled trial of children with severe acute asthma exacerbations, three doses of IB were shown to be superior to one dose or no dose of IB; all children also received three doses of albuterol. In another study of children with an initial PEFR below 50% predicted who all received albuterol and prednisone, those who also received IB had a significantly lower rate of hospitalization. A systematic review and meta-analysis of 16 trials found that combination therapy was associated with significantly lower hospitalization rates and improvements in asthma scores and pulmonary function test results.

The clinical benefits of IB may be delayed for up to 60 minutes. However, it is inexpensive and free of adverse effects, because less than 1% is systemically absorbed. IB should be given to children without moderate to severe exacerbations. Two to three doses may be mixed with three doses of albuterol and delivered continuously by NEB for 1 hour (Table 168.3). This means of administration,
Although not superior to delivery by MDI-S, will help in the delivery of three albuterol treatments in the first hour of care. Alternatively, four to eight puffs of IB may be given every 20 minutes in the first hour, along with albuterol via a MDI-S.

Moderately ill children who continue with dyspnea or significant work of breathing or poor aeration after 1 hour of continuous nebulized albuterol and IB should receive more prolonged, continuous, NEB therapy. These children treated with continuously nebulized SABAs have lower rates of hospitalization, greater improvements in PEFR, and similar rates of adverse events compared with those treated intermittently. Continuous NEB therapy will result in less respiratory therapy time and costs, has been shown to be safe, and may benefit the sickest patients the most.

The prompt use of CS can decrease the need for hospitalization and should be used routinely for patients with moderate disease. The most recent NHLBI guidelines recommend oral administration of CS; compared to intravenous (IV) or intramuscular injections, it is less invasive and benefits are equivalent. Oral CS therapy is inexpensive, with rapid gastrointestinal absorption. Children treated with frequent SABAs and oral prednisone have a reduced need for hospitalization.

A recent review of six randomized studies found similar efficacy for prednisone and dexamethasone. Dexamethasone has the advantage of having a substantially longer half-life (36–72 hours) than prednisone (18–36 hours), permitting a shorter treatment course. Children treated with dexamethasone (0.6 mg/kg) plus 1 day of additional dosing or prednisone (2 mg/kg), followed by 4 days of additional dosing, were found to have no differences in hospitalization or relapse rates. More patients in the dexamethasone group were compliant with treatment, and fewer vomited the study drug in the ED.

Most children with a moderate asthma exacerbation can be managed without the insertion of an IV line. Intramuscular therapy is a reasonable option for children who vomit orally administered CS. The use of ICS for the ED treatment of acute asthma is an area of ongoing research. Although a handful of studies have suggested potential benefits of ICS, there is not enough pediatric literature to recommend their use. Secondary to greater bioavailability and proven benefits, all moderately ill children should receive systemic CS therapy.

**Intermittent Versus Continuous Therapy.** Children requiring very frequent, intermittently nebulized albuterol may benefit from receiving albuterol continuously instead. In one clinical trial of asthmatic children, patients were randomized to receive the same total dose of albuterol nebulized intermittently or continuously over 2 hours. Those in the continuous group had a greater mean improvement in their asthma scores and significantly less respiratory therapy time, although there were no differences in mean PEFR or admission rates. A systematic review found that those treated with continuously nebulized SABAs had lower rates of hospitalization, greater improvements in pulmonary function test results, and similar rates of adverse events compared with those treated intermittently.

Perhaps the greatest advantage of continuous over intermittent therapy is one of a practical nature. It allows greater compliance with the goal of delivering the equivalent of three intermittent albuterol treatments in the first hour of care. In addition, this method will result in less respiratory therapy time and costs; it has been shown to be safe and may benefit the sickest patients the most. On the other hand, young children may not tolerate a face mask for prolonged periods.

Many emergency clinicians find it helpful to determine the total dose of racemic albuterol that would be delivered if three treatments were to be given intermittently during 1 hour, place that total dose in the NEB reservoir, and administer it continuously during 1 hour. Alternatively, a dose range may be used on the basis of the child’s weight (see Table 168.2).

A suggested approach to the management of children with moderately acute asthma is summarized in Fig. 168.1. After 1 hour of therapy, a clinical reassessment should be made; evaluation at this time is more accurate than the initial assessment at predicting the need for hospitalization. Children with decreased wheezing and work of breathing and improved aeration may be monitored without SABAs to assess their risk of clinical deterioration. Disposition decisions should be made after the child has been observed for 90 to 120 minutes from their last SABA dose. Disposition decision should take into consideration frequency of prior hospitalizations and ED visits and issues regarding compliance and support systems. ED discharge medications and education are the same as outlined for those with mild exacerbations.

Children who remain moderately ill after the first hour of continuous SABAs should remain on continuous or frequent intermittent therapy. These patients should also have received CS early in their course of treatment. If after 2 hours, the degree of respiratory distress is unchanged or worse, the patients should be hospitalized. There will be a subset of patients who demonstrate some degree of clinical improvement at the 2-hour assessment, but are not yet well enough to be sent home. One study found that among children treated with prednisone and 2 hours of SABA therapy, less than 50% were hospitalized when therapy was continued for an additional 2 hours, and none returned to the ED within 48 hours of discharge. To avoid unnecessary hospitalizations, we recommend observing patients who do not otherwise decline for a total of 3 to 4 hours prior to the decision to admit.

**Severe Exacerbation**

A severe exacerbation is characterized by restlessness or lethargy, extreme tachypnea and tachycardia, audible wheezing, inspiratory-to-expiratory ratio exceeding 1:2, significant use of accessory muscles, and oxygen saturation less than 92%. Some older children with a severe exacerbation may have bradypnea due to a prolonged expiratory phase, and auscultated wheezing may be absent with markedly decreased aeration. The PEFR will typically be less than 40% predicted, although most children will be too ill to use a peak flow meter.

Fig. 168.1 outlines the approach to management of severely ill children. They should be attached to a cardiorespiratory monitor and blood pressure cuff, with continuous monitoring of oxygen saturation by pulse oximeter. As with moderately ill children, supplemental oxygen and continuously nebulized albuterol and IB should be provided soon after arrival. Nearly all severely ill children will require more prolonged therapy with continuously nebulized albuterol, as outlined above. To achieve an oxygen saturation of 92% or greater, it may be necessary to use a non-rebreathing facemask. Severely ill children may be too sick to tolerate oral medications and may need an IV catheter. A dose of methylprednisolone should be given as soon as an IV line is established.

For children with very poor inspiratory flow, nebulized SABAs may not be effectively delivered to the smallest airways; short inspiratory time, low inspiratory pressures, and a prolonged exhalation phase will impair delivery of inhaled medications. In these cases, subcutaneous or intramuscular terbutaline or epinephrine should be used, especially if an IV line has not been established. Terbutaline has the advantages of being a more selective agent with fewer side effects, such as tremors, vomiting, or palpitations. This treatment can be of particular benefit for very ill and anxious young children who are uncooperative with the inhalation treatments. There are no data to suggest that one mode of administration is superior to the other, although intramuscular epinephrine therapy is recommended for children with...
bronchospasm due to anaphylaxis. If it is more readily available, an epinephrine autoinjector is effective for this subset of patients. Subcutaneous or intramuscular therapy may be repeated every 10 to 15 minutes, as needed, in extreme cases.

Meta-analyses have determined that the use of magnesium sulfate results in improved outcomes for adults and children. In two separate trials, children with a suboptimal response to initial SABA therapy who were randomized to receive magnesium had significantly greater improvements in pulmonary function compared with those treated with placebo. In contrast, magnesium was not found to be efficacious as a component of initial therapy for children with moderate to severe exacerbation when given prior to judging the response to early albuterol therapy.

Magnesium is inexpensive and has minimal adverse effects. It has been found to be efficacious when added to a regimen of SABA and CS therapy. Hypotension may be minimized by slowly infusing the dose over 20 minutes. Magnesium (50–75 mg/kg over 20 minutes; maximum, 2.5 g) should be given to moderately ill patients who have a suboptimal response to SABAs, IB, and CS, as well as for all severely ill children.

There are insufficient data to make recommendations for the use of IV SABAs; a systematic review of randomized controlled trials has failed to support this practice. Potential adverse effects from the use of IV SABAs are substantial and include dysrhythmias, hypertension, and hypokalemia. IV SABAs should not be used, except for impending respiratory failure, where the risk-benefit ratio shifts toward their use.

Heliox is a low-density mixture of helium and oxygen that results in less turbulent flow through narrowed airways. Theoretically, heliox may decrease the work of breathing, resulting in less respiratory muscle fatigue and lower likelihood of ventilatory failure. Heliox has not been found beneficial in all asthma exacerbations, but it may be considered for severely ill children who are not responding to more conventional therapy.

When making decisions about the need for mechanical ventilation of the severely ill patient, one should assess the entire clinical picture, including illness severity, response to therapy, and ABG results. However, the ABG results should not be used alone. The child with an initial pH of 7.10 and a PaO_2 of 55 mm Hg who appears fatigued and is not responding to therapy may not require ventilatory assistance, whereas the child with a pH of 7.18 and PaO_2 of 50 mm Hg who appears fatigued and is not responding to therapy will likely need mechanical support. Ketamine is a bronchodilator and is the drug of choice for sedation and analgesia of the asthmatic child who requires intubation.

Mechanical ventilation can result in air trapping with resultant, and enough expiratory time must be allowed for air exit from the lungs. Permissive hypercapnia describes a strategy to prevent barotrauma. It minimizes tidal volumes and respiratory rates to decrease peak inspiratory pressures.

BRONCHIOLITIS

Principles

Bronchiolitis is an acute infectious disease that results in inflammation of the small airways in children younger than 2 years. This process is manifested clinically as wheezing and increased work of breathing, along with the typical signs and symptoms of a URI. Nearly all children are affected by the viruses that cause bronchiolitis at least once during their first 2 years of life, but it is more common for infants younger than 12 months to manifest clinical signs of bronchiolitis.

Bronchiolitis is a seasonal disease, with most cases occurring between November and April in temperate climates. It is rarely fatal, with an average mortality rate of 2.0/100,000 live births in the United States. Low birth weight (<2500 g), low 5-minute Apgar score, high birth order, and young maternal age are associated with an increased risk of death. Breast-feeding, on the other hand, appears to be associated with a less severe clinical course. Many viruses are implicated as the underlying cause of bronchiolitis. Respiratory syncytial virus (RSV), the most common agent identified in children diagnosed with this disease, is estimated to cause up to 70% of cases in previously healthy children. Other viruses commonly isolated are parainfluenza, human metapneumovirus, influenza, adenovirus, bocavirus, and rhinovirus.

Most respiratory viruses that cause bronchiolitis in children are transmitted from one host to another by fomites spread from hand to nose or by droplets produced by sneezing or coughing of respiratory secretions. Sheding of the virus often begins before the onset of significant clinical symptoms and can continue for 2 to 3 weeks in an immunocompetent infant. The typical incubation period is 2 to 8 days from the time of initial contact.

In an infected patient, viral replication often begins in the epithelial cells of the upper airway before spreading to the mucosal surfaces of the lower respiratory tract. The infected epithelial cells are generally destroyed by lysis or apoptosis, which results in the desquamation of these cells and release of host inflammatory mediators. Affected lungs demonstrate epithelial cell necrosis, monocytic inflammation and edema of the peribronchial tissues, and mucus and fibrin plugging of the distal airways on histologic examination. These findings translate into the clinical findings of wheezing and lower airway obstruction in an infant with bronchiolitis. Younger infants, whose distal airways are of smaller caliber and whose immune systems lack active immunity to most respiratory viruses, are prone to more severe clinical symptoms. Severe lower airway obstruction leads to air trapping and atelectasis, resulting in mismatched ventilation and perfusion and hypoxemia. In addition, younger infants are at increased risk for fatigue, leading to hypercarbia and respiratory failure.

Clinical Features

Infants with bronchiolitis are typically younger than 12 months and present during the winter months. The first symptoms are generally those of a URI, such as nasal congestion and copious rhinorrhea. This is followed within a few days by a high fever, often associated with difficulty in feeding. Some parents will report audible wheezing as well. Approximately one-third of patients admitted with bronchiolitis will have fever. Very young infants may present with a history of apnea, which may precede the onset of typical symptoms of respiratory infection. The emergency clinician should ascertain information about the infant’s hydration status, including the amount and frequency of oral intake, urine output, vomiting, and diarrhea.

Comorbidities, such as congenital heart disease, chronic lung disease, and prematurity, can have a significant impact on the clinical course of bronchiolitis. A past history or family history of wheezing or atopy may make the diagnosis of asthma more likely, particularly in the older infant; daycare attendance and household contacts with respiratory symptoms also favor a diagnosis of bronchiolitis.

Common vital sign abnormalities include fever, tachycardia, tachypnea, and hypoxia. Pulse oximetry is noninvasive and inexpensive and provides objective data about the degree of illness of a wheezing child. The oxygen saturation (SaO_2) of any moderately or severely ill infant should be obtained soon after ED arrival as an adjunct to the physical examination. With the use of pulse oximetry, an ABG analysis is generally unnecessary to assess a patient’s oxygenation. Thus, carrying out ABG analysis should be reserved for those with severe disease and impending respiratory failure to measure the extent of hypercarbia and respiratory acidosis.

Nasal flaring and retractions are visible signs of respiratory distress. Nasal auscultation often reveals decreased air movement,
can last much longer, with a median duration of 12 days. Cough-lasting 4 weeks.

The worst phase of the illness generally occurs in the first few days, and children admitted for bronchiolitis have a median length of hospital stay of 2 to 3 days. However, the entire course of illness can last much longer, with a median duration of 12 days. Coughing and noisy breathing, in particular, can last for more than 4 weeks.

Acute bacterial otitis media is the most common associated illness, with a prevalence of up to 60%. The bacterial pathogens are similar to those recovered in other children with acute otitis media and should be treated accordingly. Other concurrent bacterial infections are rare. In one study of more than 2000 children hospitalized with RSV bronchiolitis, approximately 1% also had a urinary tract infection (UTI); no child had pathologic bacteremia or meningitis. Similar rates of UTI without bacteremia have been found in febrile children with clinical bronchiolitis, with or without documented RSV infection.

Infants younger than 8 weeks with fever and bronchiolitis present a unique dilemma for emergency clinician. The rate of serious bacterial infections (SBIs), defined as UTI, bacteremia, bacterial meningitis, or bacterial enteritis, among all febrile infants younger than 8 weeks is reported to be up to 12%. However, in infants with documented RSV infection or clinical bronchiolitis at the time of ED presentation, the incidence of an SBI is substantially lower. In a large prospective, multicenter study, 7% of febrile infants younger than 61 days who were RSV-positive had a concurrent SBI, compared with 12.5% of those who were RSV-negative. Of the patients with SBIs, most (82%) had a UTI. Bacteremia was rare and occurred only in infants younger than 1 month. None of the RSV-positive infants had bacterial meningitis. As a result, for infants between 1 and 2 months of age who are known to be RSV-positive or have clinical bronchiolitis, we recommend catheterized urinalysis and culture. Additional testing to obtain culture specimens of cerebrospinal fluid and blood may be done selectively. These infants may not require empirical antibiotic therapy for presumed SBIs: decisions to treat with antibiotics should be made on an individual basis, considering the degree of ill appearance and comorbidities. All febrile infants in the first month of life should undergo a complete laboratory evaluation for an SBI and be empirically treated with antibiotics, regardless of RSV status or presence of clinical bronchiolitis.

Apnea is commonly reported in young infants with bronchiolitis, especially those who are admitted for inpatient management. Of admitted patients, 12% have a reported history of apnea, and 5% will have apnea during the hospital stay. Risk factors for the development of in-hospital apnea include corrected age younger than 8 weeks, low birth weight, significant tachypnea or bradypnea, hypoxia, and history of apnea before admission. The absence of all these risk factors has a high negative predictive value for the development of in-hospital apnea.

### Diagnostic Considerations

#### Differential Diagnoses

Asthma is the condition that has the most clinical overlap with bronchiolitis. Physical examination findings alone cannot distinguish the two. Younger age, presentation during the winter months, antecedent URI symptoms, and absence of a prior or family history of atopic disease and wheezing suggest bronchiolitis as the cause of wheezing in an individual patient. Some infants will have clinical features consistent with both conditions. For example, a 12-month-old may present in July with a URI and wheezing for the first time. For this child, a clinician may choose to initiate therapy for acute asthma. Conditions that should be differentiated from bronchiolitis are summarized in Table 168.1.

### Diagnostic Testing

Bronchiolitis should be diagnosed primarily on the basis of history and physical examination findings. In general, viral diagnostic testing is not warranted for patients well enough for outpatient management. If test results can be obtained rapidly, identification of a viral cause may eliminate the need for further laboratory evaluation in young infants with fever. (See Chapter 166 for a comprehensive overview of recommendations for pediatric fever.)

There is tremendous variability in the use of diagnostic imaging, with some centers reporting that chest radiographs are obtained for more than 70% of infants hospitalized with bronchiolitis. In children with clinical findings typical for bronchiolitis, radiographic imaging is rarely necessary. Hyperinflation, atelectasis, and peribronchial cuffing are the findings most commonly associated with this disease. In ambulatory patients with acute lower respiratory infections, obtaining a chest radiograph does not provide additional diagnostic information, particularly if previous radiographs are available; a chest radiograph does not alter clinical management.

Management

Whereas the diagnosis of bronchiolitis is fairly straightforward, the management of children with the disease often presents emergency clinicians with confusing and controversial dilemmas. The literature is often contradictory, making it difficult to reach a consensus. As a result, there is wide practice variation in the management of bronchiolitis. However, it is clear that a consistent, evidence-based approach to this disease can lead to more efficient and effective care. Supportive care, such as providing hydration and supplemental oxygen, is the cornerstone of therapy for affected children. A management strategy, stratified by the patient’s initial degree of illness, is outlined in Figure 168.2.

SABAs are the treatment of choice for children with wheezing due to asthma. However, the evidence supporting their use in wheezing caused by bronchiolitis is less favorable than for asthma. In a meta-analysis of 22 clinical trials, a small short-term benefit in clinical score was observed for children with bronchiolitis treated with SABAs. This treatment had no significant effect on rates or duration of hospitalization. Although rare, adverse effects such as tachycardia, decreased oxygen saturation, flushing, and hyperactivity occurred more frequently in children treated with SABAs. Thus, the American Academy of Pediatrics does not recommend the routine use of SABAs for bronchiolitis; instead, emergency clinicians should consider a trial of such medications to determine if a patient has a beneficial clinical response, especially if it is unclear whether the patient has asthma or bronchiolitis.

Similar controversy exists with respect to the use of nebulized epinephrine in the treatment of bronchiolitis. A meta-analysis of 14 studies has concluded that there is not enough evidence to support the use of epinephrine for inpatients because treatment does not decrease the rate of hospitalization or the length of hospital stay for admitted patients. However, in countries where outpatient nebulized epinephrine is available, it has shown some short-term clinical benefit over other bronchodilators and placebo for outpatients. We recommend that a trial of nebulized epinephrine be considered for children with moderate to severe distress who might otherwise require more invasive interventions (eg, endotracheal intubation) secondary to disease severity. As with SABAs, nebulized epinephrine should be continued only for those patients who demonstrate a clinical benefit. There is currently no sufficient evidence to recommend the use of other bronchodilators, such as anticholinergic agents, for young children with wheezing and suspected bronchiolitis.

Many of the symptoms of bronchiolitis are a result of increased and thickened respiratory secretions. A great deal of literature supports the use of nebulized hypertonic saline in the treatment of cystic fibrosis, in which clearance of thickened secretions is vital. Although there is not yet enough literature to recommend its use in the ED definitively for bronchiolitis, several studies have suggested that nebulized hypertonic saline is a safe medication that reduces the length of stay for hospitalized children. Thus far, studies have not demonstrated any clinically significant benefits associated with its use in ED patients.

Chest physiotherapy has also been examined as a means to clear respiratory secretions. A meta-analysis of three randomized controlled trials has revealed no improvement in clinical score, length of stay, or oxygen requirement after chest physiotherapy.

Systemic CS are a well-established and effective treatment of wheezing due to acute asthma. Despite reports that more than 50% of infants may be prescribed CS when they are diagnosed with bronchiolitis, well-designed controlled trials have demonstrated no benefit for their use in terms of rate of admission, clinical score, or any other outcome. Specifically, Corneli and colleagues conducted a double-blind, randomized trial comparing oral dexamethasone with placebo in 600 children with acute moderate to severe bronchiolitis. They concluded that oral dexamethasone has no significant effect on the rate of hospitalization, respiratory status after 4 hours of observation, or later outcomes, such as length of inpatient stay, repeated medical visits, and adverse events. Although another multicenter trial did demonstrate a reduction in hospitalization rates in patients treated with the combination of oral dexamethasone and nebulized epinephrine, it is not clear that this reduction is clinically significant nor that the routine use of systemic CS for bronchiolitis has a positive effect on clinical course. Thus, our recommendation is that emergency clinicians not use CS for the treatment of bronchiolitis.

---

**Fig. 168.2.** Emergency department management of bronchiolitis. SABA, Short-acting β₂-agonist.
Because bronchiolitis is a dynamic disease, evaluations at a single point in time may not be sufficient to estimate its severity fully; thus, serial examinations are necessary. A number of demographic and clinical features have been associated with a severe clinical course. These factors include age younger than 12 weeks, history of prematurity, ill appearance, hypoxemia (SaO₂ < 95%), tachypnea (>70 breaths/min), and significant atelectasis on the chest radiograph (when obtained). In addition to younger age and prematurity, a history of hemodynamically significant congenital heart disease, chronic lung disease, and immunocompromised state have been associated with higher morbidity and mortality among inpatients.

Ultimately, the emergency clinician should assess more than just the child’s degree of respiratory distress. Patients should be admitted if they are unable to maintain oral hydration due to respiratory symptoms difficulty with breathing; or copious nasal secretions requiring frequent deep suctioning. The family or caregiver should be able to continue supportive measures at home and seek further medical care. Discharge instructions should include 24-hour follow-up with a primary care provider or emergency clinician for reevaluation. For children with a sustained clinical improvement to SABA therapy, this treatment should be continued at home every 4 hours, as needed. Although home oxygen therapy for selected patients with mild to moderate disease has demonstrated success in reducing inpatient hospitalization, primarily in high-altitude conditions, this practice requires careful coordination of care and resources, which may not be feasible in all practice settings. Furthermore, its application to children at sea level is still unclear and thus is not generally recommended. Parents should be instructed to seek immediate medical care for signs of worsening respiratory distress, including poor feeding, retractions, increased tachypnea, lethargy, and irritability.

**Prophylaxis**

Although emergency clinicians generally do not have a role in the administration of preventive medications, they should be aware that selected infants will be receiving prophylactic management. Palivizumab (Synagis) consists of monoclonal antibodies against RSV. Whereas RSV-specific immune globulin is not effective for treating the acute disease process, palivizumab is effective in reducing hospitalization rates for RSV in certain high-risk populations. It is recommended for most children younger than 24 months with chronic lung disease, congenital heart disease, or prematurity and is administered as a monthly intramuscular injection during the high-prevalence months. The emergency clinician must be aware that although preventive treatment has been initiated, treated infants with signs of bronchiolitis may still have RSV infections.
rapid bronchodilation, making subsequent aerosolized therapy effectively. In this setting, IM terbutaline is most likely to result in include those with respiratory rate more than 70 breaths/min, O2 Patients often in need of admission for bronchiolitis

**Chapter 168: Questions & Answers**

**168.1.** A 19-month-old girl with a history of asthma present with severe respiratory distress marked by wheezing, tachypnea, deep retractions, and an oxygen saturation of 92% in room air. She fails to improve 10 minutes after nebulized short-acting β-agonist (SABA) therapy and repeatedly tries to pull off her face mask. Which strategy is likely to produce the most rapid clinical benefits in this setting?

A. Administering IM terbutaline  
B. Administering IV methylprednisolone  
C. Administering the SABA via metered-dose inhaler (MDI) instead of by nebulization  
D. Doubling the dose of SABA in the nebulizer reservoir  
E. Taking off her face mask and holding it close to her face to reduce her agitation

**Answer:** A. This patient’s degree of bronchospasm and lack of cooperation make it difficult to deliver aerosolized medication effectively. In this setting, IM terbutaline is most likely to result in rapid bronchodilation, making subsequent aerosolized therapy more effective.

**168.2.** A 4-month-old male infant presents to the ED with his father, who reports that the patient has been wheezing. His vital signs are temperature, 102.2° F (39° C), respiratory rate, 50 breaths/min, and oxygen saturation, 97%. On examination, you find diffuse wheezing and copious nasal secretions. While in the ED, the patient does not have a wet diaper, and his father reports that he has had decreased oral (PO) intake for the past 2 days. Which of the following findings with bronchiolitis is not associated with the need for admission?

A. Age  
B. Decreased PO intake  
C. Oxygen saturation  
D. Respiratory rate  
E. Temperature

**Answer:** E. Patients often in need of admission for bronchiolitis include those with respiratory rate more than 70 breaths/min, O2 saturations of 95% or less, age younger than 3 months, and poor feeding.

**168.3.** Which of the following side effects are seen with the use of intravenous magnesium in the treatment of asthma in children?

A. Change in serum pH  
B. Development of a prolonged QT interval on the electrocardiogram  
C. Hypercalcemia  
D. Hyperkalemia  
E. Hypotension

**Answer:** E. Most patients who receive a magnesium infusion at the recommended dose will experience a clinically insignificant decrease in blood pressure. This may be minimized by infusing the medication over 20 minutes and by concurrently administering normal saline solution.

**168.4.** You are about to treat a child with acute asthma with albuterol. Which of the following factors is most important when considering the method of aerosolized drug delivery?

A. About 20% to 30% of nebulized drug reaches the alveoli.  
B. Children receiving β-agonists by nebulizer (NEB) have similar outcomes compared with those using a metered-dose inhaler (MDI-S).  
C. Children weighing > 20 kg should receive a maximum of four puffs of albuterol via MDI-S.  
D. MDI-S therapy is more costly than NEB therapy.  
E. The use of MDI-S for acute asthma is not supported by national guidelines.

**Answer:** B. Clinical trials and systematic reviews have repeatedly shown these two forms of therapy to be equivalent. With NEB treatment, less than 10% of nebulized drug reaches the alveoli. A recommended MDI-S dose for older children is eight puffs. Most studies demonstrate that MDI-S therapy is more cost-effective because of a slightly reduced need for hospitalization. National guidelines support the use of MDI-S to deliver albuterol to children with acute asthma.

**168.5.** A 7-month-old male infant was diagnosed 2 days ago with bronchiolitis. He continues to have wheezing and increased work of breathing, prompting his parents to bring him into the ED because of a new-onset fever. Which of the following is the most likely secondary bacterial infection in this infant with bronchiolitis?

A. Pneumonia  
B. Acute otitis media  
C. Meningitis  
D. Urinary tract infection

**Answer:** B. Bacterial acute otitis media (AOM) is the most common condition associated with bronchiolitis, with a prevalence of up to 60%. The bacterial pathogens are similar to those recovered in other children with AOM; thus, it should be treated according to standard recommendations. Other concurrent bacterial infections are rare.
Pediatric Respiratory Emergencies: Diseases of the Lungs

Genie E. Roosevelt

PNEUMONIA

Principles

Although most acute infections of the respiratory tract involve the upper respiratory tract, children frequently develop lower respiratory tract infections, most notably pneumonia and bronchiolitis. Bronchiolitis (see Chapter 168) is primarily seen in children younger than 2 years and defined as wheezing and congestion due to a viral infection. Pneumonia is an inflammation of the lung tissue that is most often due to an infection, but occasionally may follow a noninfectious insult. Although the diagnosis of pneumonia may be suggested by clinical signs and symptoms, pneumonia is typically diagnosed by an abnormal chest radiograph showing pulmonary infiltrates. The clinical picture of pneumonia is highly variable, ranging from a mild illness to life-threatening disease. Clinical and radiographic findings sometimes suggest a specific organism, but determination of a precise causative agent is not always straightforward given the limitations of diagnostic testing.

Infection rates for pneumonia in children vary inversely with age, averaging 40/1000 in preschool-age children and decreasing gradually to 7/1000 in 12- to 15-year-olds, with a male predominance of 2:1. Three-fourths of all deaths from pneumonia result from bacterial infections.

The causative organisms also vary with the age of the child. The organism is not definitively identified in most pneumonia cases, so the true incidence of the specific causative agent is unknown. Overall, viral agents cause 60% to 90% of pneumonias and are more common in younger children. Bacteria predominate in neonates but are less frequent in toddlers and older children.

Outside the neonatal period, the incidence of bacterial agents is stable throughout different age groups.1 Chlamydia trachomatis is a unique cause of pneumonia in infants 3 to 19 weeks of age.2 Bordetella pertussis classically occurs in infants younger than 1 year but may occur in older children and adolescents.3,4 Mycoplasma pneumoniae is one of the most common causes of pneumonia among children older than 5 years and may play a role in younger children.5,6 Chlamydia (formerly Chlamydia) pneumoniae is more often seen in children older than 5 years, but may cause infection in younger children.7,8

Among bacteria, group B streptococci and gram-negative bacilli predominate in neonates. Although rare, Ureaplasma urealyticum and Listeria monocytogenes may cause illness in infants younger than 2 months. Streptococcus pneumoniae is the leading bacterial cause of pneumonia in all age groups beyond the newborn period; Staphylococcus aureus and Haemophilus influenzae are less common causative agents. The incidence of H. influenzae type b disease has decreased by 90% since the onset of immunization of infants and young children.9 In 2010, the 13-valent pneumococcal vaccine (Prevnar 13, Wyeth Pharmaceuticals, NY) replaced the heptavalent pneumococcal conjugate vaccine Prevnar (Wyeth). Prevnar 13 is recommended for the primary series at 2, 4, and 6 months of age, with a fourth booster dose given at 12 to 15 months of age. Clinical trials have suggested 85% protection against serotype-specific cases of pneumococcal pneumonia.10 Studies have also shown a decrease in carriage rates of the serotypes included in daycare settings. Pneumococcal vaccine has also been shown to provide some protection against viral pneumonia. One study found a 31% reduction in the incidence of pneumonia associated with seven respiratory viruses in hospitalized children, possibly due to frequent concomitant infection of viral pneumonia with pneumococcal infection.11 Other, less common bacterial agents include group A streptococci, Neisseria meningitidis, and anaerobic bacteria, seen in the setting of aspiration pneumonia. Unusual causes of pneumonia include Pseudomonas aeruginosa, Legionella pneumophila, Pneumocystis jiroveci, and rickettsial infections. The incidence of Mycobacterium tuberculosis has been increasing in the United States, particularly in urban and low-income areas and among nonwhite racial or ethnic groups. Infants and adolescents are at highest risk in the United States.

Respiratory syncytial virus (RSV) and parainfluenza are the most frequent viral agents in infants younger than 1 year. Viruses that may be responsible for neonatal pneumonia include rubella, cytomegalovirus (CMV), and herpes simplex virus. Other viral agents include influenza, adenovirus, rhinovirus, enterovirus, measles, varicella, and Epstein-Barr virus. In addition, immunocompromised hosts are susceptible to mixed and opportunistic infections, including bacterial, viral (CMV, varicella), protozoan (P. jiroveci), and fungal disease.

Pathophysiology

The lung is protected from infection by a variety of local and systemic immune mechanisms. Passively acquired maternal antibodies are important in protection against S. pneumoniae and H. influenzae infections during the first few months of life. Children with altered protective mechanisms are at increased risk for development of pneumonia; this includes children with congenital or anatomic abnormalities (eg, cleft palate, tracheoesophageal fistula, or pulmonary sequestration), congenital cystic adenomatoid malformation, immune deficiencies, neurologic alterations that predispose to aspiration (eg, coma, seizures, cerebral palsy, general anesthesia), and alterations in quality of secreted mucus (cystic fibrosis [CF]).

Bacterial pneumonia and mycoplasmal infections are usually transmitted person to person by droplet aspiration. Asymptomatic upper airway colonization often occurs in children and may spread infection to other children. Much less commonly, bacterial pneumonia may result from hematogenous spread from a distant
focus or during primary bacteremia. Viral agents that cause pneumonia proliferate in the upper respiratory tract and spread contagiously to involve the lower respiratory tract. Viruses such as varicella, CMV, herpes simplex, Epstein-Barr, measles, and rubella also may infect the lungs through hematogenous spread.

Clinical Features

Clinical symptoms and signs of pneumonia in pediatric patients vary with patient age, specific pathogen, and disease severity. Infants younger than 3 months generally have respiratory symptoms, such as tachypnea, cough, retractions, and grunting, but may show only nonlocalizing symptoms, such as isolated fever or hypothermia, vomiting, poor feeding, irritability, and lethargy. Toddlers with *Streptococcus pneumoniae* infection may have nonspecific symptoms, such as high fever and lethargy, without significant respiratory symptoms. In general, with increasing age, signs and symptoms in children become more specific, although pneumonia in any child may have only subtle manifestations. General symptoms include fever and chills, headache, rigor, and malaise. Symptoms of lower respiratory tract disease may include cough and wheezing. Pleural irritation may cause chest, abdominal, or neck pain or result in neck stiffness. Vomiting (often posttussive) or poor oral intake is common.

Key historical factors include birth and immunization history (particularly pneumococcal and *H. influenzae* type b vaccination), sickle cell status, history of previous pneumonia or frequent infections, and presence of underlying chronic disease. Children with known respiratory (eg, bronchopulmonary dysplasia, CF) or cardiac disease tend to have more severe courses of illness; children with primary or acquired immunodeficiencies are also prone to more severe and fulminant disease from common, uncommon, and opportunistic pathogens.

The physical examination should begin with the general appearance and breathing pattern. Vital signs, including oxygen saturation, should be evaluated on arrival. Important findings include hydration status, perfusion, and level of alertness and interaction. Fever is often present with bacterial pneumonia, but may be of low grade or absent in neonates. Cardiovascular parameters may indicate dehydration or, rarely, shock. Tachypnea, although not universal, is the most sensitive indicator of pneumonia and may be the only manifestation in a young child. The World Health Organization (WHO) has published guidelines for the clinical diagnosis of pneumonia in developing countries and cites tachypnea and retractions as indicators of lower respiratory disease. Tachypnea is defined by WHO as a respiratory rate of greater than 50 breaths/min in infants younger than 1 year, more than 40 breaths/min in children 1 to 5 years of age, and more than 30 breaths/min in children older than 5 years. Other manifestations of lower airway disease may include cough, wheezing, nasal flaring, retractions, grunting, and accessory muscle use. The characteristics of the cough may aid in the diagnosis; a staccato cough in an infant may indicate pneumonia caused by *C. trachomatis* or *B. pertussis*. Auscultatory findings in an older child may include rales, wheezing, and/or diminished breath sounds. Although these may be present in younger children, the findings are much less consistent, and rales may be masked by poor inspiratory effort or noisy upper airway sounds.

Pleural irritation may cause abdominal tenderness or meningismus, and pulmonary hyperinflation may cause downward displacement of the liver and spleen. Extrapulmonary findings may include rhinorrhea, pharyngitis, or exanthems with viral infections, conjunctivitis with chlamydial disease, pharyngitis and exanthems with mycoplasmal pneumonia or extrapulmonary infections, such as soft tissue abscesses, otitis media, sinusitis, meningitis, and pericarditis, with bacterial pathogens.

Diagnostic Considerations

Differential Diagnoses

The major conditions to be differentiated in children with pneumonia include bacterial pneumonias, viral disease, other unusual infectious causes (mycobacterial, protozoal, fungal), and noninfectious pathologic conditions (Box 169.1). Certain features may help differentiate the common infectious causes (Table 169.1). Each disease entity has certain classic historical, clinical, and laboratory findings. However, the broad spectrum of illness for each condition may make an accurate diagnosis in an individual patient difficult. No specific feature reliably differentiates patients with bacterial infection from children with nonbacterial pneumonia. The health care provider should strongly consider a bacterial cause in a child with a temperature higher than 39°C (102.2°F), clinical toxicity, lobar infiltrate, or pleural effusions. Consideration of host factors, epidemiology, and the clinical picture, with judicious use of laboratory tests, generally points the emergency clinician toward the likely diagnosis and effective management.

Diagnostic Testing

Radiology. A chest radiograph is unnecessary in children without comorbid conditions who have no fever, unilateral wheezing, or tachypnea because they are unlikely to have pneumonia. A well-appearing child with cough and rales may be diagnosed clinically and treated with antibiotics as an outpatient. A child who appears ill or in whom the diagnosis is unclear requires radiographic evaluation. Radiographic findings in pneumococcal pneumonia may show an alveolar infiltrate in a patchy

Diffuse interstitial infiltrates. Viral and chlamydial infections tend to appear as diffuse interstitial infiltrates, commonly with hyperinflation and atelectasis. Chest radiographs also identify multilobar disease, pleural effusions, pneumatoceles, and pneumothorax.

Although great variability exists, bacterial pathogens classically produce alveolar infiltrates in a lobar distribution but may produce diffuse interstitial infiltrates. Viral and chlamydial infections tend to appear as diffuse interstitial infiltrates, commonly with hyperinflation and atelectasis. Chest radiographs also identify multilobar disease, pleural effusions, pneumatoceles, and pneumothorax. Hilar adenopathy may indicate tuberculosis or malignant neoplasm.

**Fig. 169.1.** Radiograph showing pneumococcal pneumonia, with infiltrate in the right upper lobe. (Courtesy Dr. Marianne Gausche-Hill.)

**Fig. 169.2.** Radiograph showing staphylococcal pneumonia, with empyema and abscess on the right. (Courtesy Dr. Brianna Enriquez and Dr. Marianne Gausche-Hill.)
Patients with pleural effusions should have lateral decubitus radiographs to assess effusion size and location. Computed tomography (CT) is useful to provide greater detail of effusions and lung abnormalities in critically ill children with complicated pneumonia. Routine CT of the chest to establish the diagnosis is not recommended.

Laboratory Studies

Any child with pneumonia is at risk for hypoxemia and should undergo pulse oximetry to determine oxygen saturation. A complete blood count (CBC) has a very limited role and is often not useful in differentiating between viral and bacterial pneumonia. A CBC should not be obtained unless the results will change management. A venous or arterial blood gas study is not needed in most patients, but may be considered in a child with severe respiratory distress to monitor the effectiveness of respiratory status or ventilation with therapy. In a well-appearing child with an uncomplicated pneumonia, a blood culture is unlikely to be helpful and should not be obtained. Blood cultures should only be considered in ill-appearing hospitalized patients. Sputum cultures may be useful for adolescents, but are technically difficult in younger children.

Patients with pleural effusions that are enlarging or compromising respiratory function should undergo thoracentesis for diagnostic and therapeutic purposes. Although parapneumonic effusions are most suggestive of bacterial infection, they also occur with mycoplasmal and occasionally with viral infections. The fluid should be sent for Gram staining and culture (anaerobic and aerobic bacterial), cell count and differential, total protein level, pH, and glucose concentration. Interpretation of pleural fluid in children follows adult guidelines (see Chapters 66 and 67). Cultures for rare pathogens may be considered if the initial assessment is not diagnostic. Bronchoscopy with bronchoalveolar lavage may be useful in a severely ill child.

Patients should not receive rapid antigen testing for viruses unless the result would change management (eg, risk stratification in a young infant with fever, consideration of using antivirals in influenza). Although most pediatric patients with tuberculosis do not have pulmonary symptoms, skin testing for tuberculosis should be considered for patients with lobar pneumonia, pulmonary effusions, or hilar adenopathy, especially in immunocompromised children or children who have recently emigrated from less developed countries. Acid-fast bacilli are more likely to appear on cultures of upper respiratory secretions usually grow normal flora or organisms that reflect only colonization. Although transtracheal sampling and direct aspiration from the lung may permit a more precise diagnosis, the invasiveness of these tests limits their usefulness.

Types of Pneumonia

Bacterial Pneumonia

*S. pneumoniae* is one of the most frequently seen bacterial agents that causes pneumonia in children. Children with immunodeficiency, chronic renal disease, functional or anatomic asplenia, and Native Americans are at increased risk for *S. pneumoniae* infection. *S. aureus* pneumonia, although less common, tends to cause a more severe pneumonia. Children with foreign body aspiration, immunosuppression, or skin infections may be at increased risk for *S. aureus* pneumonia. Progression of the disease is rapid, and empyema (90%), pneumatocele (50%) and pneumothorax (25%) are common complications (Fig. 169.2).

Before widespread immunization, *H. influenzae* type b was the second most common bacterial cause of pneumonia. However, its incidence has decreased by 90% since the onset of effective immunization. *H. influenzae* was previously considered a disease of younger children, but most cases now occur in older children. Although clinically indistinguishable from *S. pneumoniae* pneumonia, *H. influenzae* pneumonia historically had a higher incidence of associated pleural effusions (25%–75%) and bacteremia (75%–95%).

Although still uncommon, the incidence of group A streptococcal pneumonia has increased since the 1980s. Group A streptococcal pneumonia may occur sporadically and may be a complication of varicella. It is typically a severe illness with abrupt onset, rapid progression to toxicity, and high fatality rate (30%–60% fatality rate reported in a study of all ages).

In bacterial pneumonia beyond the neonatal period, fever is almost universal (often >39°C [102.2°F]). Patients may or may not have a cough and often appear relatively toxic, with tachypnea disproportionate to fever. Confined rales or wheezes and localized decreased or tubular breath sounds commonly occur in older children, whereas the physical examination in a younger child may be completely unrevealing.

The outcome of otherwise healthy children with pneumonia secondary to resistant pneumococcus currently does not differ significantly from the outcome of children with pneumonia secondary to penicillin-sensitive pneumococcus. Pneumonia caused by *S. pneumoniae* may be complicated by empyema, pleural effusion, lung abscess, and/or necrotizing pneumonia. Children who appear well can be treated with oral antibiotics. High-dose amoxicillin tid is recommended for the initial outpatient treatment of suspected pneumococcal pneumonia in otherwise healthy children, with a maximum daily dose of 2 g/day (Table 169.2). Uncomplicated bacterial pneumonia often has a rapid response to antibiotics; a stagnant or worsening clinical picture should prompt further investigation.

Viral Pneumonia

Viral pneumonia occurs more commonly in the winter and generally has a gradual onset during several days, often with associated cough, congestion, and low-grade fever. Tachypnea may be the only physical finding; however, retractions, rales, and wheezing are common. Grunting, cyanosis, lethargy, dehydration, and apnea are seen in more severely affected children. The diagnosis of viral pneumonia is often made clinically. A chest radiograph is usually not needed for the diagnosis of a child with viral pneumonia who presents during the winter months with fever, cough, congestion, and wheezing. Rapid antigen testing for RSV is not indicated unless the result would change management (eg, risk stratification in a young infant with fever). A real-time influenza polymerase chain reaction (PCR) assay may be helpful when the use of antivirals is being considered. However, children at risk (eg, children <2 years or those with significant comorbid disease) should be treated with antivirals empirically.

Radiographic findings typically include hyperinflation and peribronchial thickening, with a diffuse increase in interstitial findings. Patchy areas of consolidation may be present, representing lobular atelectasis or alveolar pneumonia. Although lobar consolidation and small pleural effusions may occur in viral pneumonia, these findings are more consistent with a bacterial cause.

Most viral pneumonias resolve without specific therapy. Because of the possibility of bacterial superinfection and the difficulty in differentiating between bacterial and viral pneumonia, antibiotics should be considered for a more severely ill child. Potential complications include dehydration, local progression of the disease, bronchiolitis obliterans, and apnea (usually in the first 3 months of life).
### Mycoplasma Pneumonia

Mycoplasma pneumonia accounts for 10% to 20% of all pneumonias and was traditionally thought to occur most commonly in 5- to 18-year-olds; however, it may also play a significant role in younger children, although still rare in infants younger than 1 year. The onset is classically gradual and insidious, but some patients may present with an abrupt onset of symptoms. Prodromal symptoms include fever, headache, and malaise, followed several days later by a nonproductive hacking cough. Patients may present with a pertussis-like illness. Other symptoms of infection may include hoarseness, sore throat, and chest pain; coryza is unusual.

Children with mycoplasma pneumonia generally appear nontoxic. Patients may have rales; wheezing occurs less often. Pharyngitis, cervical lymphadenopathy, conjunctivitis, and otitis media may occur occasionally. Rash is present in 10% of patients and may be urticarial, erythema multiforme, maculopapular, or vesicular. The course may be complicated by pneumatocele, pleural effusion, pneumothorax, or bronchiectasis. Mycoplasma, typically thought to be a benign and self-limited infection, has been shown to play a significant role in the exacerbation of asthma and may cause chronic pulmonary structural abnormalities.

*Azithromycin is not preferred in neonates due to risk of hyperbilirubinemia, particularly in premature infants.

*MRSA, Methicillin-resistant *Staphylococcus aureus.*
Chlamydial Pneumonia

*Chlamydia trachomatis* is a common sexually transmitted organism that causes cervical infection in 2% to 30% of pregnant women. It is transmitted from the genital tract of infected mothers to their newborn infants, resulting in conjunctivitis in 22% to 44% and pneumonia in 5% to 20%. An infant with pneumonia caused by *Chlamydia trachomatis* presents at 3 to 19 weeks of age after colonization at birth. The illness usually begins with nasal congestion followed by cough. In 50% of cases, conjunctivitis precedes the onset of respiratory symptoms. The infant is often afebrile and alert but tachypneic, with a repetitive staccato cough that may interfere with feeding or sleeping. It can resemble the paroxysms of pertussis and occasionally precipitates episodes of alarming respiratory distress. Mild retractions and diffuse inspiratory crepitant rales may be noted on chest examination; expiratory wheezing is usually absent or minimal. Middle ear abnormalities are present in 50% of cases.

The radiograph usually shows hyperinflation with bilateral and symmetric, diffuse, interstitial infiltrates (Fig. 169.3). Nucleic acid amplification tests have replaced culture and nonamplified detection methods (eg, direct fluorescent antibody tests) because of their higher sensitivity and specificity. Chlamydial pneumonia is often a mild illness, but may rarely be complicated by apnea and hypoxemia. Treatment with erythromycin may shorten the course; however, the disease tends to be protracted, with cough and tachypnea often requiring weeks to clear, despite antibiotics.

*Chlamydia pneumoniae* (formerly *Chlamydia pneumophilia*) is a species of *Chlamydia* that is antigenically, genetically, and morphologically distinct from other *Chlamydia* species. *C. pneumoniae* infection is transmitted from person to person, may play a role in respiratory tract infections in infants and young children, and may cause mild illness or asymptomatic infection in children and adults. Like *Mycoplasma*, *C. pneumoniae* may play a greater role in pediatric pneumonia than was previously thought. It has been reported to cause sore throat, fever, headache, pertussis-like cough, pneumonia, and influenza-like illness. Outbreaks have been reported in schools, daycare centers, military camps, adolescents, and families. Infection with *C. pneumoniae* can trigger acute episodes of wheezing in children with asthma. There are no reliable diagnostic tests to identify the organism.

Aspiration Pneumonia

Aspiration pneumonia may be due to mechanical, chemical, or bacterial causes. Bacterial aspiration occurs in children with anatomic abnormalities and central nervous system disturbances that impair normal swallowing or protective airway reflexes. Pulmonary damage results from chemical (eg, stomach acid) and bacterial (eg, gastrointestinal and upper respiratory organisms) insults. Within several hours of the aspiration, the child may have the onset of cough, tachypnea, and fever. Physical examination commonly reveals rales and wheezing with cyanosis as the disease progresses. Radiographic findings include localized (right middle lobe, right lower lobe) and diffuse, often bilateral, infiltrates.

Pneumonia in an Immunocompromised Host

Children with chronic disease and congenital, acquired, and iatrogenic immunodeficiencies are susceptible to the aforementioned respiratory pathogens and to a multitude of opportunistic organisms, including *P. jiroveci*, CMV, and fungi. Presenting symptoms may be similar to those in normal hosts; however, the course tends to be more rapid, severe, and fulminant. While awaiting organism identification and the results of culture, patients should be hospitalized for monitoring, supportive therapy, and treatment with intravenous antibiotics active against a broad spectrum of organisms. A tissue sample for diagnosis of potentially treatable organisms may need to be obtained if the patient fails to improve after initial therapy.

Complications

Several complications of pneumonia result from local and systemic effects of the infection. Pleural effusion or empyema usually accumulates with bacterial pathogens (notably *S. pneumoniae*, *H. influenzae*, and *S. aureus*) but are occasionally associated with mycoplasma, viral, and tuberculous pneumonia. Similarly, lung abscess, pneumatocele, and pneumothorax are local complications primarily seen with bacterial disease, particularly with *S. aureus*. Extensive pulmonary involvement of any cause may lead occasionally to hypoxia and progressive respiratory failure, with multiple organ failure. Apnea without other symptoms is usually seen in viral, chlamydial, and pertussis infections in infants younger than 3 months. The most common systemic complication of pneumonia is dehydration. Additional infectious foci may develop from concomitant bacteria (eg, meningitis, epiglottitis, pericarditis, septic arthritis, soft tissue infections). Viral and bacterial pneumonia are rarely associated with meningitis, encephalitis, arthritis, rhabdomyolysis, and hemolytic uremic syndrome.

Management and Disposition

Infants Younger Than 2 Months

Treatment of pneumonia in a pediatric patient consists of appropriate antimicrobial use and supportive therapy (see Table 169.2). Because of the difficulty in identifying a causative agent, antibiotic choice is generally empirical. The three most important factors in directing management are the patient’s age, likely pathogen, and degree of illness. An infant younger than 2 months with pneumonia should usually be admitted to the hospital. This age group is immunologically immature, and signs of sepsis may be subtle. Blood, urine, and cerebrospinal fluid cultures generally are indicated before the initiation of antibiotics. In infants younger than 1 month, ampicillin plus an aminoglycoside or cefotaxime, particularly in premature infants, would be appropriate choices; ampicillin and a second-generation cephalosporin should be used for infants 1 to 2 months of age. If *C. trachomatis* or *B. pertussis*

---

**Fig. 169.3.** Radiograph showing chlamydial pneumonia in an infant. Note the symmetric interstitial infiltrates. (Courtesy Dr. Michael Diament.)
is suspected, the infant should also be treated with erythromycin, azithromycin, or trimethoprim-sulfamethoxazole. Given the association of erythromycin with infantile hypertrophic pyloric stenosis, azithromycin may be the most appropriate choice.

**Infants 2 to 3 Months of Age**

Blood and urine cultures should be obtained for infants 2 to 3 months of age. The decision to perform a lumbar puncture depends on clinical suspicion of central nervous system infection. Ampicillin and a third-generation cephalosporin should be given for an infant 2 to 3 months old. If *C. trachomatis* or *B. pertussis* is suspected, the infant also should be treated with erythromycin, azithromycin, or trimethoprim-sulfamethoxazole. Supportive therapy in this age group consists of fever control and hydration. All infants should be monitored with continuous pulse oximetry for signs of needed respiratory support; apnea and respiratory failure may be precipitous.

**Infants and Children Older Than 3 Months**

In an older child, pneumonia should be categorized into likely bacterial, viral, or mycoplasmal. The emergency clinician should base the presumptive causative diagnosis on clinical and radiographic findings. A toxic child with high fever and lobar consolidation is likely to have a bacterial process, whereas a child with a disease of gradual onset, low-grade fever, and interstitial infiltrate with air trapping is more likely to have a viral process.

A well-appearing infant or preschool-age child with isolated pneumonia may be treated with outpatient oral antibiotics. In an infant beyond the neonatal period or a preschool-age child, high-dose amoxicillin (90 mg/kg/day, divided tid) is the first-line agent and will treat intermediate susceptible *S. pneumoniae*. Amoxicillin–clavulanic acid (90 mg/kg/day of the amoxicillin component, divided tid) is the second-line agent and includes some gram-negative and methicillin-sensitive *S. aureus* coverage. Oral cefprozil is relatively poorly absorbed and are highly protein-bound, resulting in inferior pharmacokinetics as compared to amoxicillin; these should be reserved for penicillin allergic patients only. Cefpodoxime 10 mg/kg/day divided bid, cefprozil (30 mg/kg/day, divided bid), or cefdinir (14 mg/kg/day, divided bid) are other options. Azithromycin should not be used to treat *S. pneumoniae* because 40% of infections are predicted to be resistant, but it is appropriate therapy for presumed atypical pneumonias in this age group. Azithromycin (10 mg/kg on day 1, followed by 5 mg/kg once daily on days 2–5) or clarithromycin (500 mg/kg/day, divided tid) is the antibiotic of choice in a school-age child or adolescent, in whom *M. pneumoniae* and *C. pneumoniae* are more common.1 Every child with bacterial pneumonia treated as an outpatient should be reevaluated within 24 to 48 hours. In patients who are febrile, dehydrated, or not clinically improved, inpatient hospitalization for parenteral antibiotic therapy should be considered. A repeat radiograph to look for progression of disease or development of a pleural effusion should also be considered.

Indications for hospitalization at the time of diagnosis include toxic appearance, vomiting or dehydration, respiratory compromise (eg, distress, hypoxia, inadequate ventilation), multilobar disease, pleural effusions, impaired immune function, and unstable social environments (Fig. 169.4). Strong consideration should be given to hospitalization of children younger than 6 months because they are prone to complications of bacterial pneumonia than older children. Supportive therapy for the inpatient should include maintenance of hydration, fever control, supplemental oxygen, ventilatory assistance, and pleural fluid drainage, as indicated. Parenteral antibiotic therapy should be administered until clinical improvement occurs.

Children with suspected bacterial pneumonia that is serious enough to warrant hospitalization should routinely be treated with parenteral antibiotics to provide reliable blood and tissue concentrations. Parenteral antibiotics for initial therapy should be considered for hospitalized patients with moderate to severe illness or those with vomiting, suspected decreased absorption, or systemic illness concerning for sepsis. For patients with mild illness, initial therapy with oral antibiotics may be considered. First-line parenteral therapy is ampicillin (150–200 mg/kg/day, q 6 hours). Ceftriaxone (100 mg/kg/day, every 12–24 hours) or cefotaxime (150 mg/kg/day q 8 hours) are second-line agents. Addition of azithromycin (10 mg/kg on day 1, followed by 5 mg/kg once daily on days 2–5) should be considered if *M. pneumoniae* is a possible causative agent. Vancomycin (40–60 mg/kg/day, divided every 6–8 hours) or clindamycin (40 mg/kg/day, divided every 6–8 hours) should be added if methicillin-resistant *S. aureus* is suspected.1

Children with neurologic or anatomic abnormalities who aspirate oral or gastric contents are susceptible to pneumonia, predominantly from anaerobes. Penicillin and clindamycin are appropriate first-line antibiotic choices. In seriously ill patients or patients not responding, agents such as metronidazole and cefotaxin may be more useful. Nosocomial infections should be treated with antibiotics also active against aerobes and gram-negative bacilli. Children with significant aspiration should be admitted to the hospital, and supportive therapy should include hydration, supplemental oxygen, and oropharyngeal suctioning.

Long-term management of a child with pneumonia should include a clinical reevaluation 2 to 3 weeks after diagnosis. If the child had a prompt response to therapy and is well at the follow-up evaluation, a repeat radiograph is unnecessary. If the child has had a complicated course (eg, pleural effusion), residual symptoms, or if the illness is not the child’s first episode of pneumonia, a chest radiograph should be obtained to ensure resolution. The follow-up radiograph should be performed 6 to 8 weeks after diagnosis.

The age of the child and clinical presentation often suggest the causative agent. The patterns of causative organisms have been changing. The spectrum of antimicrobial sensitivities also has changed, particularly with the emergence of penicillin-resistant *S. pneumoniae*.

**OTHER RESPIRATORY EMERGENCIES**

**Pertussis**

Pertussis, or whooping cough, is a respiratory tract infection usually seen in infants younger than 6 months (≈40% of cases are in children <6 months; 70% of cases are in children <5 months; 70% of cases are in children <5

![Fig. 169.4. Radiograph showing multilobar pneumonia in a child with respiratory distress. (Courtesy Dr. Marianne Gausche-Hill.)](image-url)
Because of the risk of apnea, all children younger than 6 months with presumed pertussis should be observed in the hospital for monitoring and supportive care and treated with erythromycin, azithromycin, or trimethoprim-sulfamethoxazole. Given the association of erythromycin with infantile hypertrophic pyloric stenosis, azithromycin may be the most appropriate choice. Antimicrobials have no effect on disease progression after the beginning of the paroxysmal stage but limit the spread of organisms. Vaccination of health care workers and the adult population with Tdap (tetanus, diphtheria, pertussis) has been shown to decrease rates of pertussis in infants.

Cystic Fibrosis

CF is an autosomal recessive disease caused by a mutation in the CF transmembrane conductance regulator (CFTR) gene. In whites, approximately 1 in 25 is a carrier, and the disease has an incidence of 1 in 2500 births.1 The disease also is present (in decreasing incidence) in Hispanics, Native Americans, African Americans, and Asians. Progressive lung disease and infection account for most of the morbidity and nearly all the mortality in those with CF. Defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, decreased antimicrobial effect of the airway surface, increased bacterial adherence, and innate secretion of inflammatory cytokines. All these factors result in a unique sensitivity to bacterial infection of the airway.

Pertussis is a particularly severe disease in the first year of life; complications are common and include apneic episodes, seizures, secondary bacterial pneumonia, encephalopathy, and death. Pertussis has been increasing in incidence among immunized children and young adults who have waning immunity. Adults are believed to be the reservoir for disease. The illness in these patients does not follow the classic stages as described here. These patients have a mild but prolonged course. A dry cough is the predominant symptom, often lasting 3 weeks or more.

Because of the risk of apnea, all children younger than 6 months with presumed pertussis should be observed in the hospital for monitoring and supportive care and treated with erythromycin, azithromycin, or trimethoprim-sulfamethoxazole. Given the association of erythromycin with infantile hypertrophic pyloric stenosis, azithromycin may be the most appropriate choice. Antimicrobials have no effect on disease progression after the beginning of the paroxysmal stage but limit the spread of organisms. Vaccination of health care workers and the adult population with Tdap (tetanus, diphtheria, pertussis) has been shown to decrease rates of pertussis in infants.

Cystic Fibrosis

CF is an autosomal recessive disease caused by a mutation in the CF transmembrane conductance regulator (CFTR) gene. In whites, approximately 1 in 25 is a carrier, and the disease has an incidence of 1 in 2500 births.1 The disease also is present (in decreasing incidence) in Hispanics, Native Americans, African Americans, and Asians. Progressive lung disease and infection account for most of the morbidity and nearly all the mortality in those with CF. Defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, decreased antimicrobial effect of the airway surface, increased bacterial adherence, and innate secretion of inflammatory cytokines. All these factors result in a unique sensitivity to bacterial infection of the airway.

Pertussis is a particularly severe disease in the first year of life; complications are common and include apneic episodes, seizures, secondary bacterial pneumonia, encephalopathy, and death. Pertussis has been increasing in incidence among immunized children and young adults who have waning immunity. Adults are believed to be the reservoir for disease. The illness in these patients does not follow the classic stages as described here. These patients have a mild but prolonged course. A dry cough is the predominant symptom, often lasting 3 weeks or more.
Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is defined as the need for supplemental oxygen 28 days postnatally. BPD is a common cause of diffuse lung disease in infants. Approximately 40% of children with a birth weight less than 1000 g will develop BPD. The severity of disease is related to several factors, including degree of prematurity, use of peripartum steroids, damage incurred by ventilation in the neonatal period, and nutritional status. Infants with BPD have greatly increased rates of hospitalization because of respiratory illness in the first year of life, approaching 65% in infants born weighing less than 1000 g.

Clearance of thick mucoid secretions is vital for treatment. Patients may respond favorably to bronchodilator therapy and to mucolytics, such as inhaled N-acetylcysteine, in the acute setting. Chest physiotherapy often is provided by a high-frequency oscillator device. A flutter valve or positive expiratory pressure mask also may be of assistance for improved mucoid clearance. Short-term control of inflammation may be obtained by inhaled corticosteroids.

Immunizations are vital to the prevention of pneumonia in patients with BPD. All infants 6 to 23 months old should receive the influenza vaccine during the appropriate season. The 13-valent pneumococcal vaccine and H. influenzae type b vaccine are especially vital for the prevention of bacterial pneumonia. In addition, monthly prophylaxis against RSV is administered to carefully selected patients with the monoclonal immunoglobulin palivizumab, which reduces the incidence of RSV disease and risk of subsequent hospitalization.

Patients with BPD have increased airway resistance, decreased lung compliance, and obstructive lung disease. Pneumonia in patients with BPD may be complicated by a reactive airway component. If complicated by pneumonia, radiographs show marked hyperinflation and infiltrates (Fig. 169.6). Inhaled bronchodilators may be efficacious, although these medications may worsen air exchange in patients with concomitant airway malacia. Hypoxia and hypercarbia are common, despite an increased respiratory effort. Patients with severe BPD may be receiving long-term diuretic therapy to improve lung mechanics; care should be taken not to confuse pneumonia with cor pulmonale, which can occur in younger infants with chronic supplemental oxygen requirements. Premature birth is a risk factor for reduced exercise capacity extending into adulthood.

KEY CONCEPTS

- Determining the causative agent of pneumonia by clinical presentation and radiographic findings is not reliable; empirical treatment is based on likely pathogens.
- Infants and younger children with pneumonia may have subtle or nonspecific symptoms and signs on presentation.
- First-line therapy for the treatment of bacterial pneumonia in children is amoxicillin as an outpatient and ampicillin as an inpatient.
- Pertussis should be considered in a young infant with a staccato cough or episodes of cyanosis.
- M. pneumoniae and C. pneumoniae may play a role in pneumonia in a younger child.
- In patients with CF, defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, which results in an increased likelihood for pneumonia, especially that caused by P. aeruginosa.
- CF may respond favorably to bronchodilator therapy and mucolytics, such as inhaled N-acetylcysteine.
- Patients with BPD have increased airway resistance, decreased lung compliance, and obstructive lung disease; reactive airway disease and pneumonia are common in these patients.

and symptoms, such as tachypnea, for the diagnosis of pneumonia are ill. The World Health Organization does allow for clinical signs. A chest radiograph showing pulmonary infiltrates is Answer: A.

Amoxicillin and ceftriaxone are used to treat other types of pertussis. Amoxicillin and trimethoprim-sulfamethoxazole are other possible alternatives. Other macrolides and trimethoprim-sulfamethoxazole are other possible alternatives. Amoxicillin and ceftriaxone are used to treat other types of pneumonia.

This patient likely has pneumonia caused by Bordetella pertussis. All children younger than 6 months with presumed pertussis should be observed in the hospital for monitoring and supportive care and treated with erythromycin. Other macrolides and trimethoprim-sulfamethoxazole are other possible alternatives. Amoxicillin and ceftriaxone are used to treat other types of pneumonia.

Which of the following findings is necessary to make the diagnosis of pneumonia in children requiring admission to the hospital?
A. Abnormal chest radiograph showing pulmonary infiltrates
B. Fever and decreased breath sounds unilaterally
C. Fever and rales
D. Rales and tachypnea

Answer: A. A chest radiograph showing pulmonary infiltrates is necessary to make the diagnosis of pneumonia in children who are ill. The World Health Organization does allow for clinical signs and symptoms, such as tachypnea, for the diagnosis of pneumonia in resource-poor areas. However, in the United States with easy access to radiological services, children should have an abnormal radiograph showing pulmonary infiltrates prior to hospitalization for the diagnosis of pneumonia. Infectious Disease Society of America guidelines allow for the treatment of clinical pneumonia if community-acquired pneumonia (CAP) is strongly suspected and the child does not have respiratory distress.

Which of the following statements best describes the epidemiology of pneumonia in children?
A. Bordetella pertussis is the most common cause in infants.
B. Haemophilus influenzae type b is still an important pathogen.
C. Listeria monocytogenes may cause illness in children younger than the age of 5 years.
D. Viral agents are the most common cause of pneumonia in children overall.

Answer: D. Viral agents are the most common cause of pneumonia in children. Bacteria predominate in neonates but are less common causative agents in toddlers and older children. Although L. monocytogenes may cause pneumonia in infants, it is unusual after 3 months of age. H. influenzae type B has decreased by 90% since the onset of immunization of infants and young children.

What is the most common viral agent causing pneumonia in infants younger than 1 year?
A. Adenovirus
B. Enterovirus
C. Epstein-Barr virus
D. Respiratory syncytial virus (RSV)

Answer: D. RSV and parainfluenza are the most common viral agents in infants younger than 1 year. Viruses that may be
169.5. Which of the following conditions may predispose children to a bacterial pneumonia?
   A. All of these
   B. Cystic fibrosis
   C. Foreign body aspiration
   D. Immunosuppression

**Answer:** A. All these conditions predispose children to severe pneumonia—foreign body aspiration because of obstruction and resulting inflammation with secondary infection, immunosuppression with unusual organisms such as Pseudomonas, and cystic fibrosis, for the inability to clear mucus in the lung itself, resulting in increased risk of infection.

169.6. A 2-month-old presents with a persistent cough for 2 weeks and intermittent episodes of posttussive vomiting. Which of the following tests is the most accurate to establish a diagnosis?
   A. Blood culture
   B. Direct fluorescent antibody
   C. Polymerase chain reaction assay of nasal aspirate
   D. Sputum culture

**Answer:** C. This clinical scenario depicts a young infant with possible pertussis. Although culture may be highly specific, it often yields false-negative results. The most accurate test at this time is the polymerase chain reaction. Blood cultures are unreliable in cases of pertussis and are only positive in less than 10% of children with bacterial pneumonia overall.

169.7. Which of the following strategies has been shown to be most effective in decreasing the rates of pertussis in infants?
   A. Postexposure prophylaxis with a macrolide for family members of index cases
   B. Vaccination of all infants at 2 months of age
   C. Vaccination of health care workers in the adult population
   D. Vaccination of school-age children

**Answer:** C. Vaccination of health care workers in the adult population with Tdap (tetanus, diphtheria, pertussis) has been shown to decrease rates of pertussis in children. All other strategies have been less effective.

169.8. A 2-year-old presents with fever, cough and rales. Chest radiograph reveals right middle lobe pneumonia. Which of the following antibiotics would be recommended for outpatient treatment for this toddler who is not penicillin allergic?
   A. Amoxicillin
   B. Azithromycin
   C. Ceftriaxone
   D. Cephalexin

**Answer:** A. High-dose amoxicillin, 90 mg/kg/day, divided tid is the treatment of choice for children with pneumonia younger than 5 years. Once the child reaches school age, then macrolides (eg, azithromycin) are suggested as empirical therapy because of the increased risk of *Mycoplasma pneumoniae* infection.
Pediatric cardiac disease traditionally has been divided into congenital and acquired disorders, with a further subdivision of the congenital heart disorders into cyanotic and acyanotic lesions. From a purely clinical standpoint, however, children with cardiac disorders present to the emergency department (ED) in one of two scenarios. In the first scenario, the child has signs and symptoms that may represent an exacerbation or complication of an already known underlying cardiac disorder. In cases with a known underlying cardiac disorder, early consultation with the child’s cardiologist along with comparisons of the child’s previous and most recent diagnostic cardiac studies, such as chest radiographs, electrocardiograms (ECGs), and echocardiograms are very useful in the evaluation and management phases.

The second scenario represents more of a challenge to the emergency clinician: the child with an undiagnosed congenital or acquired cardiac disorder who presents with concerning signs and symptoms (Box 170.1). This chapter focuses on some of the more common and life-threatening cardiac disorders in infants and children who present to the ED, with an emphasis on rapid evaluation, stabilization, and management of these disorders.

Fetal and Neonatal Circulation

Some key features of fetal circulation that differ from that of the child are the presence of the ductus venous, the ductus arteriosus, and a patent foramen ovale. During fetal development, blood oxygenated by the placenta flows to the fetus through the umbilical vein, bypasses the fetal liver through the ductus venous, and returns to the fetal heart through the inferior vena cava. Blood returning from the inferior vena cava then enters the right atrium and is preferentially shunted to the left atrium through the patent foramen ovale (Fig. 170.1). Blood in the left atrium is then pumped from the left ventricle to the aorta. The oxygenated blood ejected through the ascending aorta is preferentially directed to the fetal coronary and cerebral circulations.

Deoxygenated blood returns from the superior vena cava to the right atrium and ventricle to be pumped into the pulmonary artery. Fetal pulmonary vascular resistance (PVR), however, is higher than fetal systemic vascular resistance (SVR); this forces deoxygenated blood to mostly bypass the fetal lungs (see Fig. 170.1). This poorly oxygenated blood enters the aorta through the patent ductus arteriosus and mixes with the well-oxygenated blood in the descending aorta. The mixed blood in the descending aorta then returns to the placenta for oxygenation through the two umbilical arteries.

Once the infant is delivered and the umbilical cord is cut, expansion and aeration of the lungs cause a decrease in PVR, which enhances pulmonary blood flow. Increased global oxygenation causes a physiologic closure of the umbilical arteries, umbilical vein, ductus venous, and ductus arteriosus. Increasing pulmonary blood flow to the infant’s left atrium promotes closure of the foramen ovale. Complete anatomic closure of the foramen ovale does not occur until about 3 months of age. Although the ductus arteriosus functionally closes at about 10 to 15 hours of life, complete anatomic closure does not occur until 2 to 3 weeks of life.

In the absence of any congenital cardiac defects, these transitional circulatory changes pose no physiologic problems to the infant. However, closure of the ductus arteriosus can cause life-threatening complications in neonates, with specific congenital cardiac defects, who are dependent on the patency of the ductus arteriosus for survival.

Pathophysiology of Cardiovascular Compensatory Responses

There are two fundamental and clinically useful physiologic formulas to keep in mind during the clinical assessment and management of cardiac disorders:

Cardiac Output = Stroke Volume × Heart Rate

Blood Pressure = Cardiac Output × SVR

The young myocardium is inefficient and unable to increase its contractility in response to demand. When more cardiac output is needed, infants and children respond with an increase in heart rate. Therefore, bradycardia in infants and young children is an ominous sign that connotes a severely compromised cardiac output. Children develop the adult capacity to increase their stroke volume to improve overall cardiac output by 8 to 10 years of age.

On the basis of the first physiologic formula, as stroke volume decreases, a compensatory increase in the heart rate will be necessary to preserve a normal cardiac output. A decrease in stroke volume can be caused by a weak “pump,” decreased volume in the circulation, or both. The most common cause of decreased stroke volume in children is hypovolemia from dehydration. Other causes of decreased stroke volume in children are listed in Box 170.2.

Tachycardia is the first compensatory cardiovascular response when stroke volume is decreased. If tachycardia alone is not enough to maintain a normal cardiac output, the next compensatory physiologic mechanism to preserve perfusion is an increase in the SVR. This change in SVR is exhibited as an increase in the diastolic blood pressure, which in turn accounts for a narrowed pulse pressure. The clinical examination findings of the extremities of a child with an increased SVR include pallor, mottling, cool skin, delayed capillary refill time (>2 seconds), and weak or thready distal pulses.

Pathophysiology of Cyanosis

Cyanosis is a clinical sign caused by the presence of deoxygenated blood in the capillary beds, most readily observed in the mucous membranes, conjunctiva, nail beds, and skin. For cyanosis to be evident clinically, there must be at least 4 to 5 g/dL of deoxyhemoglobin admixed in the blood; this correlates with an oxygen...
saturation of approximately 80% to 85%. That is, children with anemia—even if hypoxic—may not show overt signs of cyanosis (i.e., the critical mass of deoxygenated hemoglobin is not met to manifest cyanosis clinically). Central cyanosis results from a decrease in pulmonary ventilation and oxygenation, a decrease in pulmonary perfusion, the shunting of deoxygenated blood directly into the systemic circulation, or the presence of abnormal hemoglobin. Cyanosis in the neonate may be due to a variety of cardiac, pulmonary, hematologic, or toxic causes. Cardiac causes of cyanosis include congenital lesions with right-to-left shunts and cardiac lesions with decreased or increased pulmonary blood flow. Common pulmonary causes of cyanosis include bronchiolitis, pneumonia, and pulmonary edema. Methemoglobinemia is one of the hematologic causes of cyanosis.

**Clinical Features of Cyanosis**

The region of the body that is cyanotic can provide important clinical clues to the cause of the cyanosis. Central cyanosis involves the lips, tongue, and mucous membranes, whereas peripheral cyanosis (acrocyanosis) involves the hands and feet. Acrocyanosis is a common finding in neonates caused by cold stress and peripheral vasoconstriction. Central cyanosis reflects a pathologic origin and is an ominous sign. Infants with cyanosis secondary to a congenital heart defect may not exhibit as much respiratory distress compared with the infant with cyanosis due to a pulmonary cause. Thus, a cardiac cause of central cyanosis should be suspected in a child who appears “comfortably blue.” Another important clinical clue to the cause of central cyanosis is that cyanosis of cardiac origin usually worsens with crying, whereas cyanosis due to a pulmonary cause may improve when the infant cries. Cyanotic congenital heart defects with right-to-left shunting will demonstrate a minimal improvement with supplemental oxygen, whereas cyanosis of a purely pulmonary origin typically exhibits a significant improvement with supplemental oxygen (Table 170.1).

**CLINICAL FEATURES AND DIAGNOSTIC TESTING: THE CARDIAC EVALUATION**

The key elements that should be elicited in the history of a child with a known underlying cardiac disorder are listed in Box 170.3.
**TABLE 170.1**

**Clinical Clues to Help Distinguish Between Cardiac and Pulmonary Causes of Central Cyanosis**

<table>

*Cyanosis due to severe pulmonary disease (eg, severe pneumonia, tension pneumothorax, acute chest syndrome of sickle cell disease) may not show significant improvement with supplemental oxygen, but these children will also typically exhibit severe respiratory distress along with clinical cyanosis.

**Box 170.3**

**Key Elements to Elicit in the History of a Child With a Known Cardiac Disorder**

**Cardiac Diagnosis**

Congenital or acquired disorder?

Any episodes of previous decompensation? (If so, are the current signs and symptoms similar to or different from those previous episodes?)

**Oxygen Issues**

Currently receiving home oxygen supplementation (continuous or only during feedings and sleep)?

Baseline oxygen saturation (room air or while receiving home oxygen)?

Any recent need for increasing the amount of supplemental oxygen?

**Medications**

Names and dosages of all current medications (cardiac and noncardiac medications)?

Were any of these cardiac medications stopped recently (by the cardiologist or parental noncompliance)?

Any recent increases in the cardiac medications (reasons for the increase, previous dosage versus the current dosage, and the date this dosage was increased)?

Any new cardiac medications added recently and the reason for these additions?

Recent digoxin level if the patient is receiving daily digoxin therapy?

**Results of Most Recent Studies (Chest Radiograph, Electrocardiogram, Echocardiogram, and Cardiac Catheterization)**

When were the last studies performed, and what were the results? Why were those studies performed (routine follow-up studies or obtained because of decompensation from baseline, or a planned evaluation for an upcoming surgical procedure)?

**Surgical Procedures**

Previous procedures and complications?

Any future planned procedures?

Early consultation with the child’s cardiologist or cardiac surgeon is extremely useful.

In addition to a well-focused history and physical examination, a chest radiograph and an ECG should be obtained for any child with a known or suspected cardiac disorder. Other useful ancillary studies include an arterial blood gas analysis, hemoglobin and hematocrit levels, digoxin levels in those patients receiving daily digoxin, serum electrolyte values in those patients receiving daily diuretic therapy, and the 100% oxygen (hyperoxia) challenge.

**History**

Certain maternal medical conditions are associated with a higher incidence of cardiac disorders, such as congenital heart blocks from maternal systemic lupus erythematosus and cardiomyopathy in infants of diabetic mothers.

Infants with an underlying congenital heart disorder may exhibit diaphoresis during feeds and poor weight gain secondary to congestive heart failure (CHF). The cause of the infant’s hypoxia—cardiac or pulmonary—may be ascertained by the age at onset and the events surrounding a change in color. For example, an infant who sweats during feeding may exhibit a splanchnic steal from anomalous coronary arteries, causing transient ischemia, pain, color change, and diaphoresis that resolve after eating. A child with an undiagnosed congenital heart defect resulting in CHF and pulmonary edema may take longer to feed, frequently pausing to catch his or her breath, with subsequent poor weight gain and gradually increased work of breathing. Respiratory tract infections are common during childhood and may cause an acute deterioration in a child with an underlying cardiac disorder. In turn, children with congenital heart disease (CHD) with large left-to-right shunts and increased pulmonary blood flow tend to have a higher incidence of lower respiratory tract infections. Acute respiratory distress in these patients may be from a combination of pulmonary and cardiac factors (eg, CHF).

**Chest Pain**

Common causes of pediatric chest pain are musculoskeletal chest wall pain, costochondritis, asthma exacerbation, pneumonia, pleurisy, gastritis, and gastroesophageal reflux. An often underdiagnosed cause of acute chest pain in the child or adolescent is precordial catch syndrome (also known as Texidor’s twinge). The pain is sharp, non-radiating, and located in the left periapical area of the chest wall; it occurs suddenly, is often worsened by inspiration, and is not associated with dyspnea. The child may report that the pain “took my breath away” or that “I was afraid to move”; the pain typically resolves within a few minutes and is not associated with dysrhythmias or other sequelae. The pathophysiologic mechanism of precordial catch syndrome is unknown; the pain may originate from the parietal pleura or costal cartilage. Patients often have some relief by taking a slow, deep breath, stretching, or massaging the chest wall. If an ECG and a chest radiograph are performed, findings are typically normal. The pain is fleeting but may recur at any time and at any age. Management includes administering pain control as needed and reassuring family members that their child’s chest pain is not of cardiac origin.

Chest pain or syncope on exertion may be due to an underlying cardiac condition and deserve a more thorough investigation, especially if there is a positive family history of sudden unexplained death in young adulthood. Myocardial injury due to drug abuse (eg, stimulants such as cocaine, methamphetamine, synthetic or over-the-counter drugs of abuse) should be considered. Pulmonary embolism is a possible cause of chest pain, especially in pregnant adolescent girls, patients taking oral contraceptive agents, or those with blood dyscrasias. The rare though life-threatening condition of aortic dissection should be considered as a cause of chest pain in a patient with physical examination stigmata that are suggestive of a collagen vascular disorder, such as Marfan syndrome. Patients with a known congenital heart defect or an acquired cardiac disorder (eg, Kawasaki disease, acute rheumatic heart disease, myocarditis, pericarditis, cardiomyopathy) who present with chest pain or unexplained shortness of
breath prompt a more thorough diagnostic evaluation, including serial cardiac biomarkers and ECGs.

**Physical Examination**

**General Appearance and Pulses**

All four extremities should be palpated for the presence and quality of pulses. In infants, feel for the brachial and femoral pulses. Bounding pulses are typically present in infants with a patent ductus arteriosus. Coarctation of the aorta should be suspected in any child with strong or unequal pulses in the upper extremities and weak pulses in the lower extremities. The pulse may be weak and thready in all extremities in a child who presents with CHF and shock.

**Vital Signs and Blood Pressures**

A mild resting tachypnea or tachycardia may be the only clinical clue to an underlying cardiovascular disorder. A simplified table of normal pediatric vital signs may be used at the bedside (Table 170.2). Methods to calculate normal expected blood pressures and hypotensive blood pressures are also listed in Table 170.2.

To measure blood pressure accurately, use a cuff that covers two-thirds of the upper arm or thigh. A cuff that is too narrow will overestimate the patient’s true blood pressure; conversely, a cuff that is too large will underestimate the true blood pressure. Measure blood pressures in both arms in children with a suspected cardiac disorder. As an example, coarctation of the aorta (proximal to the origin of the left subclavian artery) may present with a left arm blood pressure significantly lower than the right arm. Measure blood pressures in the thighs in any child with a suspected aortic coarctation or with documented hypertensive blood pressures in the upper extremities. The mere presence of femoral pulses does not rule out clinically the possibility of a coarctation of the aorta. Even with an appropriately sized cuff, the blood pressures in the thighs can be 10 to 20 mm Hg higher than the blood pressures in the upper extremities because of the lack of well-designed blood pressure cuffs for the legs. Therefore, if the measured blood pressure in the lower extremities is lower than the blood pressure in the upper extremities, coarctation of the aorta should be suspected. Pulse oximetry readings that are lower in the legs than in the upper extremities are also suggestive of either a coarctation of the aorta or a right-to-left-shunt across a patent ductus arteriosus.

**Cardiac Auscultation**

The intensity and degree of splitting of the S2 heart sound (closure of the pulmonic and aortic valves) are extremely important in a pediatric cardiologic evaluation. In normal children, both components (aortic closure and pulmonic closure) of S2 should be heard along the left upper sternal border (the pulmonic area). A widely split and fixed S2 suggests a physiologic problem resulting from either a constant volume overload to the right side of the heart (eg, atrial septal defect [ASD]) or a pressure overload to the right side of the heart (eg, pulmonic stenosis). An ASD classically presents as a widely split and fixed S2. The intensity of the S2 component may be louder than normal in the child with pulmonary hypertension.

The third heart sound (S3) is best heard along the lower left sternal border or the apex and may be a normal finding in children and young adults. S3 is produced by a rapid filling of the ventricles and is heard during early diastole, just after the S2 sound. A loud S3, however, is pathologic and due to dilated ventricles from volume overload (eg, CHF and large ventricular septal defects [VSDs]). The fourth heart sound (S4) occurs late in diastole, just before the S1 sound. The finding of an S4 is due to a decrease in compliance of a stiff, hypertrophic ventricle, best heard at the apex with the patient in the left lateral decubitus position.

Cardiac murmurs are produced by turbulent blood flow through the heart. The presence of a cardiac murmur may not be associated with an underlying cardiac defect. The location, intensity, quality, timing, and radiation of the murmur determine whether the murmur is suggestive of an underlying cardiac pathologic condition. Although systolic murmurs can be present without any underlying anatomic abnormalities, diastolic murmurs are always considered pathologic in nature. Other criteria that suggest an underlying anatomic cardiac abnormality are listed in Box 170.4. Murmurs may be difficult to appreciate in the noisy ED setting, especially in tachycardic children. However, the location of the murmur may be a valuable clinical tool in determining the underlying anatomic origin of the murmur (Box 170.5).

Murmurs without any underlying anatomic abnormalities or hemodynamic significance are termed innocent or functional murmurs. All innocent murmurs are associated with normal ECGs and normal chest radiographs. Two of the most common innocent murmurs encountered in the pediatric population are the neonatal pulmonic flow murmur (peripheral pulmonic stenosis murmur) and Still’s murmur. The pulmonic flow murmur of the neonate is due to the relatively thin walls and angulation of the right and left pulmonary arteries at birth. This systolic murmur is best heard at the left upper sternal border with radiation throughout the entire chest, axilla, and back. It usually disappears by 3 to 6 months of age. Persistence of a systolic murmur in the pulmonic area beyond this period should raise the possibility of a pathologic pulmonary arterial stenosis.

Another common innocent murmur in children is Still’s murmur, in children between 2 and 6 years of age. Best heard along the left midsternal border, this murmur has a vibratory, musical, or twanging quality resulting from turbulent flow. The distinct quality of Still’s murmur distinguishes it from a VSD murmur, which has a harsher quality. The intensity of Still’s murmur increases in the supine position, or with fever, excitement, exercise, or anemia; like most murmurs, it is best heard with the bell of the stethoscope.

**Hyperoxia Test**

The hyperoxia test is an important bedside diagnostic tool to help differentiate between cardiac and pulmonary causes of central cyanosis. This test consists of assessment of the rise in arterial oxygenation with the administration of 100% oxygen. An arterial blood gas is measured after several minutes on high-flow oxygen (100% oxygen). When the child is breathing high-flow oxygen, an arterial oxygen partial pressure (\(P_{aO_2}\)) of more than 250 mm Hg virtually excludes hypoxia due to CHD—a “passed” hyperoxia test. An arterial oxygen reading of less than 100 mm Hg (in a child without obvious pulmonary disease) is consistent with a right-to-left shunt and is highly predictive of CHD—a “failed” hyperoxia test. Values between 100 and 250 mm Hg may indicate lesions with intracardiac mixing. Pulse oximetry is not an appropriate substitute for an arterial blood gas analysis; it is not sensitive enough to determine “pass or fail” of the test because a child breathing high-flow oxygen and registering 100% on pulse oximetry may actually have a \(P_{aO_2}\) anywhere between 80 and 680 mm Hg. Prolonged administration of 100% oxygen may cause some theoretic problems, such as closure of the ductus arteriosus in those infants with critical left-sided heart obstructions or pulmonary vasodilation (which would potentially worsen pulmonary vascular congestion). Oxygen should not be initially withheld in critically ill infants based on this concern alone; rather, providers should closely monitor the response to oxygen in infants with suspected CHD.

**Arterial Blood Gas Analysis**

Patients with CHF exacerbation may exhibit respiratory acidosis (low pH and high \(P_{aCO_2}\)) in addition to a low \(P_{aO_2}\) due to worsening respiratory fatigue, which initially may be subtle clinically. In contrast, children with compensated cyanotic congenital heart defects may have a normal pH despite a (chronically) low \(P_{aO_2}\). Chronic mild hypoxemia causes a chronic mild acid load on the respiratory, renal, and blood buffer systems; acute illness such as a respiratory infection can rapidly cause a decompensation in this fragile balance, resulting in a worsening acidosis. Patients with congenital heart defects who are not experiencing respiratory compromise are unlikely to exhibit elevation in \(P_{aCO_2}\). Any cardiac condition that results in inadequate tissue perfusion (ie, any of the acyanotic congenital heart defects that result in CHF) will exhibit a metabolic acidosis with or without respiratory compensation.

**Hemoglobin and Hematocrit Levels and Serum Electrolyte Values**

The hemoglobin and hematocrit levels may reveal a compensatory physiologic elevation (ie, polycythemia) in children with cyanotic congenital heart defects. Any concurrent medical illness or blood loss could precipitate an acute deterioration by compromising the oxygen-carrying capacity in children with an underlying congenital heart defect. Hemoglobin and hematocrit levels are also helpful in evaluating whether a child’s pallor is due to CHF or anemia. Serum electrolyte values may be helpful in the evaluation of children with acute dysrhythmias or suspected metabolic acidosis and those children who are receiving chronic diuretic therapy.

**Chest Radiography**

Three important features of the chest radiograph (Fig. 170.2) are the cardiac size (cardiothoracic ratio), the cardiac shape (silhouette), and the degree of pulmonary vascular markings. The easiest method to gauge heart size in children is to determine the cardiothoracic ratio: compare the largest transverse diameter of the cardiac shadow on the posteroanterior view of the chest radiograph with the widest internal diameter (measured from the inside rib margin at the widest point above the costophrenic angles) of the chest. The films should be obtained during maximal inspiration whenever feasible.

The normal cardiothoracic ratio in children is 50% to 55%. The cardiothoracic ratio is not very accurate in preverbal children, in whom a good inspiratory view is rarely obtained.
suggestive of an endocardial cushion defect, VSD, ASD, or patent ductus arteriosus.

In a normal left-sided aortic arch, the aorta descends to the left of the midline and slightly displaces the tracheal air shadow toward the right of midline above the level of the carina. With a right-sided aortic arch, the tracheal air shadow may be midline or deviated toward the left. A right-sided aortic arch is found in up to 25% of the children with tetralogy of Fallot. Rib notching secondary to increased collateral blood flow along the intercostal vessels can sometimes be appreciated between the fourth and eighth ribs in older children with undiagnosed coarctation of the aorta.
aorta (Fig. 170.5) but is rarely visualized in children with coarctation of the aorta who are younger than 5 years old.

Electrocardiography

Electrocardiographic findings in infants and children change according to the child’s age (Table 170.3).\(^7\)\(^8\) At birth, the muscle mass of the right ventricle is greater than that of the left ventricle; this is demonstrated by right axis deviation on the neonatal ECG. By the end of the first month of life, the left ventricle assumes dominance. By 6 months old, the left ventricular to right ventricular mass ratio is 2:1, which then reaches the adult ratio of 2.5:1 by adolescence. The durations of the PR interval, QRS complex, and QT intervals increase with age.

Left axis deviation is present when the QRS axis is less than the lower limit of normal for the child’s age; it occurs with left ventricular hypertrophy and left bundle branch block. Right axis deviation is present when the QRS axis is greater than the upper limit of normal for the child’s age; it occurs with right ventricular hypertrophy and right bundle branch block. A “superior” QRS axis (0 to −180 degrees with an S wave in aV\(_F\) greater than the R wave) may be suggestive of an endocardial cushion defect or tricuspid atresia.

Some of the more common indications to obtain an ECG in a pediatric patient include chest pain, dyspnea, syncope, palpitations, suspected dysrhythmias, or an underlying cardiac disorder. A rare but potentially fatal congenital cardiac abnormality detected by ECG, anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA), will show ischemic changes. These infants have a history of poor feeding, irritability, and failure to thrive, then suddenly present with cardiogenic shock secondary to myocardial ischemia.

Biochemical Markers

As in adults, cardiac troponin T (cTnT) and cardiac troponin I (cTnI) are highly sensitive and specific in children for myocardial damage.\(^7,\)\(^8\) Reference values are slightly higher for neonates younger than 3 months; normal and indeterminate values will depend on the bioassay used. The indications for troponin testing in children include suspected cardiac ischemia (of any etiology), myocarditis, and myocardial dysfunction in sepsis syndrome. Several studies have supported the use of plasma B-type natriuretic peptide (BNP) levels in the assessment and management of CHF in adults. Elevated BNP levels have demonstrated a similar correlation in children with CHF. BNP levels also correlate with the clinical symptoms of heart failure and ejection fraction.\(^9\)\(^10\)

SPECIFIC DISORDERS

Congenital Heart Disease

In the United States, the incidence of CHD has remained fairly constant at approximately 1%, or 8 to 10 cases per 1000 live births. This equates to approximately 32,000 infants born each year with some form of CHD (Table 170.4). Although a large percentage of CHD is now detected with prenatal sonograms, pulse oximetry before discharge from the nursery is an inexpensive screening tool for CHD, especially useful in resource-poor settings.\(^11\)\(^-\)\(^13\)

Clinical Features

Age, severity of symptoms, and time of presentation of a child with CHD vary by the specific defect, complexity, severity, and timing of the normal physiologic changes that occur as the fetal circulation transitions to that of a neonate (Table 170.4). The more severe or complex CHD lesions may not be clinically apparent immediately after birth. As the ductus arteriosus begins to close in the first several weeks of life, cardiac defects with obstructive lesions of the pulmonary or systemic circulations will be unmasked, and these infants will present with acute cyanosis, shock, or both. In general, the more severe the anatomic defect is (ie, lack of pulmonary blood flow or lack of systemic blood flow), the earlier in life these conditions will be manifested with cyanosis and shock.

Many children with CHD do not fit neatly into a single pattern; some have mixed defects. The exact anatomic diagnosis of a CHD is dependent on echocardiography, cardiac catheterization, or...

Advanced imaging; establishment of the exact anatomic diagnosis is seldom possible in the ED setting.

## Diagnostic Testing

The emergency clinician should rely on several key elements of the clinical evaluation in addition to findings on the chest radiograph and ECG to narrow the diagnostic possibilities. Pattern recognition may be helpful (Box 170.6). For example, the presence of cyanosis, a grade 3/6 systolic ejection murmur best heard at the mid left sternal border, a boot-shaped heart, and a decreased pulmonary blood flow on the chest radiograph with evidence of right ventricular hypertrophy on the ECG suggest tetralogy of Fallot.

## Management

The majority of children who present to the ED in shock are volume depleted or septic. These patients should receive rapid repeated fluid boluses of 20 mL/kg. Children with poor perfusion and suspected CHD, however, should receive smaller aliquots of 10 mL/kg to avoid precipitation or exacerbation of CHF. In this
Box 170.6 Clinical Clues to Aid in the Diagnosis of Congenital Heart Disease

**PRESENCE OR ABSENCE OF CENTRAL OR PERIPHERAL CYANOSIS?**
Central cyanosis with minimal respiratory distress ("comfortably blue") is suggestive of CHD more than of a purely pulmonary etiology.

**ABNORMALITIES IN CARDIAC AUSCULTATION?**
Murmurs: Systolic versus diastolic, location, and radiation
Quality of S1, S2, and the presence of any clicks or gallops

**CHANGE IN THE DEGREE OF CENTRAL CYANOSIS WITH CRYING?**
Worsening of cyanosis with crying suggests a cardiac rather than a purely pulmonary etiology.

**RESPONSE OF PAO2 TO THE HYPOXIA CHALLENGE (ADMINISTERING 100% OXYGEN)?**
Purely pulmonary causes of cyanosis: PaO2 should rise to levels above 250 mm Hg
Cyanotic CHD associated with an increased pulmonary blood flow: PaO2 may occasionally reach as high as 150 mm Hg
Cyanotic CHD associated with a decreased pulmonary blood flow: PaO2 will not rise above 100 mm Hg

**CHEST RADIOGRAPH ABNORMALITIES?**
Cardiac size and shape (one of the three classic cardiac silhouettes)?
- Boot-shaped heart: Tetralogy of Fallot
- Egg-on-a-string silhouette: Transposition of the great vessels
- Snowman-shaped or figure-of-eight heart: Total anomalous pulmonary venous return

**DEGREE OF PULMONARY BLOOD FLOW?**
Increased (acyanotic): ASD, Eisenmenger's syndrome, VSD, patent ductus arteriosus, endocardial cushion defects
Increased (cyanotic): Transposition of the great arteries, total anomalous pulmonary venous return, hypoplastic left heart syndrome, truncus arteriosus
Decreased or normal (acyanotic): Pulmonic stenosis, aortic stenosis, coarctation of the aorta
Decreased (cyanotic): Tetralogy of Fallot, severe pulmonic stenosis, Ebstein's anomaly, tricuspid atresia, pulmonary atresia, hypoplastic right heart syndrome

**ELECTROCARDIOGRAPHIC ABNORMALITIES?**
Evidence of chamber enlargement: right ventricular hypertrophy, left ventricular hypertrophy, biventricular hypertrophy, right atrial hypertrophy, or left atrial hypertrophy
An abnormal superior QRS axis is suggestive of endocardial cushion defect or tricuspid atresia.

---

Box 170.7 Ductal-Dependent Cardiac Lesions in the Neonate

**CONGENITAL HEART DISEASES THAT REQUIRE A PATENT DUCTUS ARTERIOSUS TO PRESERVE BLOOD FLOW FROM THE AORTA TO THE PULMONARY CIRCULATION**
- Tetralogy of Fallot
- Tricuspid atresia
- Pulmonary atresia
- Hypoplastic right heart syndrome
- Transposition of the great vessels

**CONGENITAL HEART DISEASES THAT REQUIRE A PATENT DUCTUS ARTERIOSUS TO PRESERVE BLOOD FLOW FROM THE MAIN PULMONARY ARTERY TO THE SYSTEMIC CIRCULATION**
- Severe coarctation of the aorta
- Severe aortic stenosis
- Hypoplastic left heart syndrome

Closure of the ductus arteriosus in these patients interrupts blood flow to the lungs, producing cyanosis (eg, tricuspid atresia), or disruption in blood flow to the systemic circulation and shock (eg, hypoplastic left heart syndrome). PGE1 infusion is typically started at 0.05 to 0.1 µg/kg/min. A known adverse reaction to a PGE1 infusion is apnea (30%). Assiduous monitoring of the child’s respiratory drive is essential with PGE1 administration. Although some small studies endorse the omission of endotracheal intubation of neonates on a PGE1 infusion, endotracheal intubation should be considered for these infants, especially before inter-facility transport.

Children with cardiac conditions are at risk of post-intubation cardiovascular collapse due to positive pressure ventilation, increased intrathoracic pressures, and decreased venous return (eg, cyanotic heart disease is often preload dependent). To support cardiac output and SVR (which mitigates a right-to-left shunt), ketamine is the preferred induction agent along with a nondepolarizing metabolically neutral neuromuscular blocker, such as rocuronium. Not only will intubation provide a secure airway, but controlled ventilation will also help decrease the infant's work of breathing, shunting much needed cardiac output and metabolic demands from the overtaxed respiratory apparatus. Other adverse reactions to a PGE1 infusion include fever, seizures, bradycardia, hypotension, flushing, and decreased platelet aggregation.

**Acyanotic Congenital Heart Defect**
Acyanotic CHD can be further subdivided (Fig. 170.6) into obstructive lesions (eg, pulmonic stenosis, aortic stenosis, coarctation of the aorta) and lesions characterized by left-to-right shunting with an associated increase in pulmonary blood flow (eg, VSDs, ASDs, patent ductus arteriosus, endocardial cushion defects). These acyanotic lesions usually present within the first 6 months of life with symptoms of CHF; however, ASDs can remain asymptomatic until adulthood.

**Ventricular Septal Defect**
VSD is the most common congenital cardiac defect and accounts for 20% to 25% of all cases of CHD. Spontaneous closure occurs in 30% to 40% of all VSDs overall and in 50% to 70% of smaller VSDs.4

**Clinical Features** The degree of symptoms is dependent on the size of the VSD and the degree of peripheral vascular resistance (PVR). Most VSDs are clinically asymptomatic (minimal or no
Clinical Features. Large ASDs or those associated with comorbid conditions, such as bronchopulmonary dysplasia, can be manifested with symptoms of CHF and pulmonary overcirculation (eg, dyspnea with feedings, poor weight gain, and frequent lower respiratory tract infections). The majority of ASDs are discovered when a suspicious murmur is detected on a routine physical examination. A widely split and fixed S2 is a characteristic finding of ASDs.

Diagnostic Testing. The chest radiograph of children with ASDs will reveal varying degrees of cardiomegaly, right atrial and right ventricular enlargement, and a prominent main pulmonary artery segment and increased pulmonary vascular markings. The ECG will reveal varying degrees of right axis deviation and right ventricular hypertrophy. All patients with unrepaired ASDs will have symptoms if pulmonary hypertension develops. Patients with large ASDs that are not detected and repaired are at risk for development of Eisenmenger’s syndrome. Unlike VSDs, uncomplicated ASDs are not associated with high risk of bacterial endocarditis because of the lower turbulence and velocity of blood flow through the atrial defect.

Management. The traditional closure of ASDs required open heart surgery to place a patch over the septal defect. Newer therapies involving closures with septal occluder devices placed by the transcatheter approach have been described. Antiplatelet therapy during the 6-month period after placement of the device is typically given and is safe and effective in preventing thrombus formation on the surface of the septal occluder device.

Eisenmenger’s Syndrome. Eisenmenger’s syndrome can occur in any large left-to-right shunt defect that is not surgically corrected. Left uncorrected, irreversible changes in the pulmonary arterioles leads to pulmonary vascular obstruction and pulmonary hypertension. As the degree of pulmonary hypertension increases, the PVR may then begin to exceed the SVR. This causes right-sided pressures to exceed those on the left, causing right-to-left shunting. The reversal in the direction of shunt flow produces cyanosis. Other clinical features of patients who have Eisenmenger’s syndrome include chest pain, dyspnea on exertion, and hemoptysis.

Coarctation of the Aorta. Coarctation of the aorta accounts for approximately 8% of all CHD, and up to 50% of patients with coarctation of the aorta also have an associated bicuspid aortic valve. The area of coarctation can occur proximal to the insertion of the ductus arteriosus (predisental type) or distal to the insertion of the ductus arteriosus (most common, postdental type).

Clinical Features. The severity of the symptoms and the age at time of presentation are dependent on the location of the coarctation, the degree of narrowing, and the presence of any other associated cardiac defects. Infants with the rarer, preductal type of coarctation of the aorta may also exhibit differential cyanosis if the ductus arteriosus remains open. With differential cyanosis, the upper half of the body is perfused with well oxygenated blood supplied by the left ventricle and the ascending aorta. However, the lower half of the body will appear cyanotic, because it is largely perfused by right-to-left shunting of deoxygenated blood from the patent ductus arteriosus into the descending aorta. Infants with the postdental type of coarctation of the aorta will present with signs of circulatory failure and shock when the ductus arteriosus begins to close. The clinician should search for a “brachial-femoral delay” by palpating both pulses simultaneously.

Most of the asymptomatic cases of the more common postdental coarctation of the aorta are diagnosed as a result of a cardiology referral for a systolic murmur or a hypertension evaluation, but infants with severe postdental coarctation of the aorta can also present during the first few weeks of life with signs of circulatory failure and shock. If a child is discovered to have hypertension on a routine physical examination, obtain blood pressure measurements in the lower extremities to assess the possibility of coarctation of the aorta. Systolic blood pressure in the legs is typically slightly higher than in the arms. Coarctation of the aorta should be suspected if the systolic blood pressure in the right arm is 15 to 20 mm Hg higher than that in the legs. If the systolic pressure
in the right arm is higher than that in the left arm, the area of coarctation is probably preductal and located proximal to the origin of the left subclavian artery. In general, diastolic blood pressures are similar in the upper and lower extremities.

**Diagnostic Testing.** The chest radiograph will most often reveal a normal-sized cardiac silhouette and normal pulmonary vascular markings, but notching along the lower borders of the posterior fourth to eighth ribs due to the pressure of the dilated collateral vessels may be exhibited in children older than 5 years old. The ECG typically reveals a left axis and left ventricular hypertrophy. Suspected cases of coarctation of the aorta should be imaged with transthoracic echocardiography or cardiac magnetic resonance imaging to confirm and to define the coarctation. In stable patients, this can be done on an outpatient basis.

**Management.** Definitive surgical repair of coarctation of the aorta involves angiography or stenting of the narrow aortic lumen; resection of the narrowed section of the aorta with an end-to-end anastomosis may be necessary. Complications of undiagnosed coarctation include systemic hypertension, heart failure, hypertensive encephalopathy, and intracranial hemorrhages.

**Cyanotic Congenital Heart Diseases**

Cyanotic CHDs are a result of either decreased pulmonary blood flow to the lungs or right-to-left shunting of desaturated blood directly into the systemic circulation (Fig. 170.7). The classic cyanotic CHD can be remembered by the five Ts: truncus arteriosus, transposition of the great arteries, tricuspid atresia, tetralogy of Fallot, and total anomalous pulmonary venous return. Other forms of cyanotic CHD include Ebstein's anomaly, pulmonary atresia, severe pulmonary stenosis, hypoplastic left heart syndrome, and hypoplastic right heart syndrome. Many of these cyanotic heart lesions are routinely detected either on prenatal ultrasound or in the nursery; only tetralogy of Fallot is covered in this section.

**Tetralogy of Fallot.** Tetralogy of Fallot accounts for approximately 10% of all cases of CHD and is the most common cause of cyanotic CHD beyond infancy. Tetralogy of Fallot is often associated with other cardiac defects, such as right-sided aortic arch (25% of patients), ASD (10% of patients), and anomalous origin of the left coronary artery. Tetralogy of Fallot arises from a single embryologic defect in which the subpulmonic conus fails to expand, resulting in the four abnormalities (Fig. 170.8): (1) right ventricular outflow tract obstruction; (2) large, unrestrictive, malaligned VSD; (3) over-riding aorta that receives blood flow from both ventricles; and (4) right ventricular hypertrophy secondary to the high pressure load placed on the right ventricle by the right ventricular outflow tract obstruction. These anatomic defects collectively result in decreased pulmonary blood flow and varying degrees of right-to-left shunting of deoxygenated blood across the VSD.

**Clinical Features.** The degree of cyanosis and the age at presentation are directly dependent on the degree of right ventricular outflow tract obstruction. Infants with tetralogy of Fallot typically have worsening of their cyanosis during crying and feeding. Older children with tetralogy of Fallot may have cyanotic exacerbations during periods of physical exertion. Infants with milder forms of right ventricular outflow tract obstruction may be acyanotic and are sometimes referred to as having a “pink” tetralogy of Fallot. Infants with severe right ventricular outflow tract obstruction exhibit profound cyanosis within the first few days of life and may even require PGE1 infusion to preserve pulmonary blood flow by left-to-right shunting from the aorta.
Management of Tetralogy of Fallot Hypoxic Spells

Place the child in the knee-to-chest position to increase the systemic vascular resistance (SVR), which decreases the right-to-left shunt across the ventricular septal defect (VSD).

Provide supplemental oxygen (limited value by itself). Morphine: 0.1 to 0.2 mg/kg IV or IM

Fentanyl: 1 µg/kg/dose IV or IM as an alternative to morphine

Fentanyl: 2 µg/kg/dose intranasally (anatomic limit of 1 mL solution per naris)

Midazolam: 0.2 to 0.3 mg/kg/dose intranasally (anatomic limit of 1 mL solution per naris)

Sodium bicarbonate: 1 mEq/kg IV if suspected or documented acidosis

Consider ketamine: 1 to 2 mg/kg IV or 3 to 5 mg/kg IM

Consider propranolol: 0.01 to 0.2 mg/kg IV

Consider phenylephrine: 0.01 to 0.02 mg/kg IV

IM, Intramuscular; IV, intravenous.

These hypoxic spells are characterized clinically by periods of hyperpnea, uncontrollable crying, and worsening cyanosis. Limpness, seizures, cerebrovascular accidents, and even death have been reported with more severe tet spells. During a tet spell, the intensity of the murmur decreases because of less blood flow through the right ventricular tract obstruction and more blood being shunted from the right ventricle to the left ventricle through the VSD.

Management. The overall treatment goals for tet spells are to increase the SVR, to abolish the hyperpnea, and to correct the metabolic acidosis (Box 170.8). Give supplemental oxygen and increase the child’s SVR by placing him in a knee-to-chest position; older children may be placed in the squatting position, if tolerated. Both maneuvers are believed to increase SVR and to decrease the pathologic right-to-left shunting of blood. Analgesics should be given to calm the child, decrease the catecholamine surge, and decrease the respiratory rate. Morphine (0.1 to 0.2 mg/kg intramuscularly has been a traditional option but has the possible untoward effect of systemic vasodilation (further decreasing the SVR) by endogenous histamine release. Fentanyl and midazolam are newer options without the potential risk of endogenous histamine release. Both may be given via the intranasal route and may be less distressful than intramuscular morphine. Ketamine (1 to 2 mg/kg IV or 3 to 5 mg/kg IM) is a good choice for its analgesic and sedative effects; it is an excellent choice to improve SVR, metabolic acidosis, sodium bicarbonate (1 mEq/kg IV) may be given to break the cycle of hypoxemia, acidosis, and worsening hypotension and perfusion. Most infants respond to these measures and exhibit an improvement in their oxygenation and a decrease in their degree of cyanosis.

Infants whose condition does not improve with these measures may require a vasopressor (such as, phenylephrine) to increase the SVR and thereby to decrease the degree of right-to-left shunting across the VSD. An intravenous fluid bolus may also be considered to increase the volume of blood flow through the pulmonary artery. If the aforementioned pharmacologic interventions are not successful, consider propranolol (0.1 to 0.25 g/kg IV) administered slowly and repeated if needed every 10 to 15 minutes (possibly reduces infundibular spasm at the right ventricular outflow tract) or phenylephrine (5 to 20 mcg/kg IV) administered slowly and repeated if needed every 10 to 15 minutes (alpha-antagonist to increase SVR).

Fig. 170.9. Pathophysiologic mechanisms of a hypoxic (tet) spell. PaO2, Arterial oxygen partial pressure; PCO2, partial pressure of carbon dioxide in the arterial blood; SVR, systemic vascular resistance; VSD, ventricular septal defect.
Palliative surgical procedures to increase the amount of blood flow temporarily to the pulmonary arteries are performed in infants with severe cyanotic tetralogy of Fallot. The most commonly performed procedure is the modified Blalock-Taussig shunt, in which an anastomosis is created between the subclavian artery and the ipsilateral pulmonary artery. Definitive surgical repair consists of closing the VSD and opening the right ventricular outflow tract obstruction by resection of the infundibular tissue. The mortality rate is 5% to 10% within the first 2 years after definitive surgical repair in uncomplicated tetralogy of Fallot cases. Complications that can occur after definitive surgical repair include complete heart block, ventricular dysrythmias, and right bundle branch block (secondary to the right ventriculotomy).

### Postoperative Complications of Congenital Heart Defects

A variety of postoperative complications can be seen in patients who present to the ED weeks to months after cardiac surgery: thrombosis of a shunt-conduit with decreased flow; increased shunt-conduit flow with resultant CHF; atrial and ventricular dysrythmias; heart block; myocardial ischemia; and endocarditis. The size of the cardiac silhouette and the degree of pulmonary blood flow on the chest radiograph may provide valuable clues as to whether there is an increased or decreased blood flow through a surgical conduit that was created to provide an improvement in blood flow to the pulmonary system.\(^{20,27}\) Comparison of the child’s other postoperative chest radiographs can help determine whether there has been a change in the heart size and pulmonary vascularity.

The post-pericardiectomy syndrome is an inflammatory pericarditis that can occur 1 to 6 weeks after any surgical procedure that involved a pericardiectomy. An immunologic inflammatory response is believed to occur from blood in the pericardial sac. This syndrome is characterized by fever, chest pain, and pericardial effusion. A pericardial friction rub may be heard, depending on the amount of fluid that accumulates in the pericardial sac. The chest radiograph may reveal an enlarged cardiac silhouette, and the echocardiogram will confirm the diagnosis. Pericardiocentesis is rarely required but may be necessary if the amount of pericardial effusion is significant enough to cause a pericardial tamponade. The majority of cases will resolve within 2 to 3 weeks with bed rest and nonsteroidal antiinflammatory medication.

### Respiratory Syncytial Virus Infections in Infants and Children With Congenital Heart Defects

Respiratory syncytial virus (RSV) is the most common cause of lower respiratory tract infections in infants and children worldwide, with the majority of children infected at least once by 2 years of age. Reinfection occurs commonly throughout life.\(^{25-30}\) Children with CHD who have RSV infections tend to have a higher rate of intensive care unit (ICU) admissions and require mechanical ventilation more frequently than those children who do not have CHD. Children with CHD who require hospitalization for RSV infection have a fatality rate that is two to six times greater than that of children without CHD.\(^{29}\) RSV infection in a child with CHD carries a 40% mortality rate—70% in children with CHD and associated pulmonary hypertension. Therefore any infant with CHD and acute RSV infection should be admitted for observation (Box 170.9).

### Congestive Heart Failure

#### Perspective

CHF is defined as a clinical syndrome in which the cardiac output is unable to meet the hemodynamic and metabolic demands of the body. Although there is a wide array of causes of CHF, the primary cause in infants and children is CHD, which results in volume or pressure overload. Other causes of CHF include the anomalous left coronary artery in infants, myocarditis, endocarditis, rheumatic heart disease, pericardial effusions, anemia, cardiomyopathies, systemic hypertension, hypothyroidism, hyperthyroidism, electrolyte imbalances, endocrine disorders, cardiac toxins, and dysrythmias that compromise cardiac output.

CHF can result from a derangement in any of the four primary determinants of normal cardiac function: (1) excessive preload (eg, large left-to-right shunts and severe chronic anemia); (2) decreased cardiac contractility (eg, myocarditis); (3) excessive afterload (eg, left-sided obstructive lesions); and (4) rhythm abnormalities that compromise cardiac output or stroke volume (eg, paroxysmal supraventricular tachycardia and severe forms of heart block). The treatment of CHF depends on which of these four primary determinants of normal cardiac function are compromised. For example, inotropic agents and diuretics may be required in a child with volume overload and decreased cardiac contractility, whereas vasodilatory agents may be required in a child with CHF due to an increased afterload.

#### Clinical Features

Although the clinical manifestations of CHF depend on the exact pathophysiologic cause of the CHF, common presenting signs and symptoms include tachycardia, gallops (especially an S₃), tachypnea with rales, hepatomegaly, peripheral edema, and decreased peripheral perfusion of the extremities. Wheezing and a chronic cough may also be the presenting symptoms of CHF.

#### Diagnostic Testing

The chest radiograph typically reveals an enlargement of the cardiac silhouette and varying degrees of pulmonary congestion. An echocardiogram will be able to assess the ejection fraction, as well as to identify underlying anatomic defects. Plasma BNP may be helpful in differentiating cardiac from pulmonary causes of dyspnea in children.

#### Management

Acute stabilization of any child who presents with CHF includes administration of supplemental oxygen and agents to augment cardiac contractility and to improve cardiac output. Children with respiratory distress due to pulmonary congestion may benefit from elevation of the head and upper torso—if available, place the infant in his car seat. Continuous positive airway pressure (CPAP) or biphasic positive airway pressure (BiPAP) ventilation via mask or nasal cannula (nasal CPAP) may be useful initially to

### Box 170.9

#### Conditions Associated With an Increased Risk of Severe or Fatal Respiratory Syncytial Virus Infections

- Cyanotic or complex congenital heart defects
- Pulmonary hypertension
- Prematurity (especially those infants with bronchopulmonary dysplasia or chronic lung disease)
- Immunodeficiency states
Children who present in severe respiratory distress secondary to pulmonary edema may require intubation to support oxygenation and ventilation. Plasma BNP levels have been used also to monitor the response to treatment regimens in patients with CHF. Diuretics and inotropic agents may be considered. Furosemide (Lasix) in a dose of 1 mg/kg is the most common loop diuretic used to increase renal perfusion and to improve urine output. In contrast to adults, nitroglycerin is not first-line therapy for CHF in children. Children are much more sensitive to the drug’s potent vasodilatory effects than adults, and they can experience profound and rapid hypotension with its administration.

The best vasopressor for decompensated pediatric cardiogenic shock is currently under debate and investigation. Traditionally, dopamine was administered for undifferentiated shock in children; however, other agents with less arrhythmicogenic side effects are available. Increasingly, guidelines advocate for an approach based on etiology and pathophysicsiology. Norepinephrine is a good choice as a first-line vasopressor for pediatric decompensated cardiogenic shock due to its effectiveness in supporting SVR.

Dobutamine may be added for its selective cardiac inotropic effects. Epinephrine is also potent inotrope and chronotrope that increases the SVR.

Amrinone and milrinone, most commonly used in the ICU setting, may be added to an inotrope to promote forward blood flow via peripheral vasodilatory effects. These agents have been used to improve cardiac index in septic shock and to prevent low cardiac output states for children with CHD. Side effects of these medications include profound hypotension, dysrhythmias, hypersensitivity reactions, fever, hepatotoxicity, and thrombocytopenia.

Pediatric Dysrhythmias

The most common cause of cardiopulmonary arrest in infants and children is the untreated progression of respiratory failure or shock rather than a primary cardiac dysrhythmia. Accordingly, the most common arrest rhythm is asystole or bradycardia rather than ventricular fibrillation or ventricular tachycardia. Drugs of abuse (eg, cocaine and crystal methamphetamine, among others) and overdose of prescription medications (eg, cyclic antidepressants) should be considered in the evaluation of any previously healthy adolescent patient who presents with an acute dysrhythmia. Even medications used to treat underlying cardiac problems (such as, digoxin, amiodarone, and procainamide) can themselves precipitate dysrhythmias.

Pediatric dysrhythmias can be divided into three broad categories of rhythms by their effect on the child’s pulse: slow (sinus bradycardia and heart blocks), fast (supraventricular tachycardia or ventricular tachycardia with a pulse), or absent (ventricular tachycardia without a pulse, ventricular fibrillation, pulseless electrical activity, or asystole). The most common dysrhythmia in children is supraventricular tachycardia, which occurs most commonly in infants and young children. Although supraventricular tachycardia can spontaneously occur in infants without any underlying structural cardiac defects, ventricular tachycardias typically are due to an underlying myocardial abnormality.

Clinical Features

Rhythm disturbances in infants can be manifested with symptoms, such as fussiness, lethargy, poor feeding, pallor, respiratory distress, or cardiogenic shock. Older children present with chest pain, palpitations, difficulty in breathing, or syncope. The type and degree of severity of the presenting signs and symptoms should be taken into account in the evaluation and management of the specific dysrhythmia in each case (Box 170.10).

MANAGEMENT

Is the child hemodynamically stable or unstable?

If a pulse is present, is it slow or fast?

Children who have a pulse with good perfusion parameters (ie, an alert child with strong distal pulses, warm extremities, and brisk capillary refill times) do not require emergency intervention unless they exhibit a rhythm that has the potential to rapidly degenerate into a more serious condition. Children who exhibit electrocardiographic evidence of conduction abnormalities (eg, Mobitz type II second-degree heart block, complete heart block, prolonged QT intervals, or aberrant conduction, such as the Wolff-Parkinson-White syndrome) may require emergent management, depending on symptoms and hemodynamic status.

Although some medications can be used to treat only atrial tachycardia (eg, adenosine for supraventricular tachycardia) or ventricular tachycardia (eg, lidocaine for ventricular tachycardia), amiodarone and procainamide can be used for an array of both atrial and ventricular dysrhythmias, including supraventricular tachycardia and ventricular tachycardia. 38-40

Bradydysrhythmias

Sinus Bradycardia. Bradycardia is defined as a heart rate that is slower than the lower limit of normal for a child’s age. According to the current definition by the American Heart Association (AHA) guidelines in pediatric advanced life support (PALS), clinically significant bradycardia in children is a heart rate slower than 60 beats/minute that is associated with poor systemic perfusion. An athletic adolescent may have a resting baseline heart rate lower than 60 beats/minute, requiring no treatment if asymptomatic with good perfusion.

Bradycardia is poorly tolerated in infants and children because they are not physiologically capable of increasing their stroke volume to maintain an adequate cardiac output in the face of significant bradycardia. The most common cause of symptomatic bradycardia in infants and children is hypoxia. First, ensure adequate oxygenation and ventilation. Epinephrine is the first-line medication for treatment of symptomatic bradycardia in children.

### BOX 170.10

**Conditions Associated With a High Risk for Development of Dysrhythmias**

- Congenital heart defects (uncorrected defects and postoperative complications)
- Congenital complete heart blocks (eg, maternal systemic lupus erythematosus)
- Myocarditis
- Rheumatic heart disease
- Kawasaki disease with involvement of the coronary arteries
- Cardiomyopathy
- Prolonged QT syndrome
- Aberrant atrioventricular conduction pathways (eg, Wolff-Parkinson-White syndrome)
- Electrolyte abnormalities (eg, potassium, calcium, and magnesium disturbances)
- Commotio cordis
- Profound hypothermia
- Hypoxia
that is not responsive to appropriate oxygenation and ventilation. If additional doses of intravenous or intraosseous epinephrine are required to treat symptomatic bradycardia, the dose should remain at standard dosing (0.01 mg/kg). Atropine is indicated for vagally-induced bradycardia or treatment of primary atrioventricular block. Atropine will have no effect on the denervated heart (e.g., after cardiac transplantation). If vascular access is not available, both epinephrine and atropine can be administered through the tracheal tube, although the intravenous route is preferred.

Other causes of bradycardia include hypothermia, increased intracranial pressure, heart blocks (congenital and acquired), denervated heart status after cardiac surgery, hypothyroidism, sick sinus syndrome, and various medications and toxins (e.g., digoxin, beta-blockers, calcium channel blockers, and cholinergic agents). Children with presyncopal or syncopal symptoms or poor perfusion with Mobitz type II second-degree atrioventricular block, complete third-degree heart block, or sick sinus syndrome should be paced.

Tachydysrhythmias

**Supraventricular Tachycardia.** Supraventricular tachycardia is the most common symptomatic dysrhythmia in infants and children. No cardiac abnormalities are found in approximately half of the cases; the Wolff-Parkinson-White syndrome is present in only 10% to 20%. The QRS complex is narrow (<0.08 second) in up to 90% of the cases of pediatric supraventricular tachycardia. The type of supraventricular tachycardia that occurs most commonly in infants and children involves a reentrant mechanism that uses an accessory pathway and the atrioventricular node (i.e., atrioventricular reentrant tachycardia [AVRT]). The orthodromic reentry phenomenon involves the normal antegrade conduction from the atria to the ventricles down the atrioventricular node with retrograde conduction back from the ventricles to the atria by the accessory pathway. Orthodromic conduction will produce a narrow–QRS complex supraventricular tachycardia. The less common reentry mechanism is the antidromic form in which conduction from the atria to the ventricles first goes antegrade down the accessory pathway then retrograde back to the atria by the atrioventricular node. Antidromic conduction will produce a wide–QRS complex supraventricular tachycardia. Supraventricular tachycardia in a child with a preexisting bundle branch block can also result in a wide-complex supraventricular tachycardia (Fig. 170.10). The ECG in Figure 170.10 reveals a case of a wide-complex supraventricular tachycardia in a child with Ebstein’s anomaly of the tricuspid valve who also presented with CHF (Fig. 170.11).

**Clinical Features and Diagnostic Testing.** The width of the QRS interval in patients with pediatric supraventricular...
Tachycardia is most commonly narrow complex, with heart rates in infants usually higher than 220 beats/minute (Fig. 170.12). It is sometimes difficult to distinguish between sinus tachycardia and supraventricular tachycardia (Table 170.6).

Although healthy infants can generally tolerate supraventricular tachycardia with heart rates approaching 300 beats/minute, supraventricular tachycardia may begin to produce signs of CHF and shock if it is left untreated. Older children with supraventricular tachycardia commonly present with palpitations, difficulty in breathing, and chest discomfort.

**Management.** The emergency clinician should immediately synchronize cardioversion (0.5 to 1 J/kg) for children in supraventricular tachycardia (SVT) with signs of poor perfusion, such as altered mental status, delayed capillary refill, pallor, cyanosis, or hypotension (ie, decompensated shock). If the child does not convert with this initial cardioversion attempt, the energy dose can be doubled up to 2 J/kg on subsequent attempts. If the child is hemodynamically stable, vagal maneuvers, then adenosine, may be attempted initially before cardioversion; a continuous rhythm strip should be run to document the response to each conversion attempt. Vagal maneuvers (eg, a bag containing a slurry of crushed ice and water to the face, blowing on an occluded straw, or blowing on the tip of a syringe) can be attempted before adenosine administration in the child with hemodynamically stable supraventricular tachycardia. Application of ice to the face has been demonstrated to be a fairly effective method of converting supraventricular tachycardia in infants and children. One method to perform this maneuver is to fill a plastic bag or surgical glove with a slurry of crushed ice and water, which is then placed over the infant’s forehead, eyes, and bridge of the nose for 10 to 15 seconds. Placement of the ice bag should not occlude the nose or mouth. External ocular pressure should be avoided; it can be dangerous.
in children because excessive pressure can lead to a ruptured globe. Carotid massage is less effective and is not recommended as a vagal maneuver in infants or children.37

The initial dose of adenosine in children is 0.1 mg/kg with a maximum initial dose of 6 mg. If this initial dose of adenosine fails to convert the supraventricular tachycardia, the dose is then doubled to 0.2 mg/kg with a maximum of 12 mg/dose. This 0.2 mg/kg dose of adenosine may be repeated once. Higher doses can be used in younger children (0.3 mg/kg) but doses should not exceed the adult maximum of 12 mg. Elective cardioversion with procedural sedation may be required in children who fail to convert with adenosine. Adenosine-induced wide-complex tachycardia (secondary to an occult accessory conduction pathway) is an uncommon complication (Fig. 170.13). Amiodarone may be given at a loading dose of 5 mg/kg over 60 minutes, then continued at 5 mcg/kg/min.41 Verapamil should be avoided in infants and children younger than 2 years old because of the risk of profound hypotension and cardiovascular collapse in this age group.42-44 Once the patient has converted to sinus rhythm, a 12-lead ECG should be obtained to assess for the possibility of Wolff-Parkinson-White syndrome or any other underlying conduction abnormalities that may have predisposed the child to development of the supraventricular tachycardia.

### Atrial Flutter and Atrial Fibrillation
Both atrial flutter and atrial fibrillation are rare in children and are usually associated with underlying heart conditions (eg, CHD, status post–open heart surgical procedures that involved the atria, myocarditis, and digoxin toxicity). Hemodynamic stability of these two dysrhythmias depends on the rate of the ventricular response. As in adults, children with hemodynamically unstable atrial flutter or atrial fibrillation should be cardioverted. The initial treatment priority in patients with hemodynamically stable atrial flutter and atrial fibrillation is first to slow the rate of the ventricular response with medications, such as diltiazem, beta-blockers, or digoxin. Once the ventricular rate is controlled, the rhythm can then be

| TABLE 170.6 |
| Clinical and Electrocardiographic Features to Differentiate Sinus Tachycardia From Supraventricular Tachycardia in Children |
| Precipitating events | SINUS TACHYCARDIA | SUPRAVENTRICULAR TACHYCARDIA |
| P waves on electrocardiogram (ECG) | Present | Absent |
| Heart rate varies with activity | Yes | No |
| Beat-to-beat variability | Yes | Constant R-R intervals |
| Heart rate in infants (beats/minute) | Usually <220 | Usually >220 |
| Heart rate in children (beats/minute) | Usually <180 | Usually >180 |

Fig. 170.13. An example of adenosine-induced wide-complex tachycardia. A dose of 6 mg of adenosine was administered to this previously healthy 15-year-old girl who presented with a 6-hour history of palpitations. She had no previous cardiac problems except for intermittent palpitations in the past that always resolved spontaneously without any medical interventions. Once adenosine blocked the conduction through the atrioventricular node, a wide-complex tachycardia appeared on the electrocardiogram (ECG), which was probably due to antegrade conduction through an accessory pathway. During the 30 seconds of this wide-complex tachycardia, the patient remained alert with excellent perfusion parameters. This wide-complex tachycardia then spontaneously converted to normal sinus rhythm. Although the patient's postconversion ECG did not reveal an accessory pathway, Holter monitoring 1 month later detected the classic electrocardiographic findings of Wolff-Parkinson-White syndrome.
converted and suppressed with amiodarone, propranolol, or elective cardioversion. If the patient who presents with atrial flutter or atrial fibrillation is known to have an underlying Wolff-Parkinson-White syndrome, the four medications that should be avoided are the A-B-C-D medications (adenosine, beta-blockers, calcium channel blockers, and digoxin); all of these medications preferentially block conduction down the atrioventricular node, leaving the accessory pathway open to conduct the atrial tachycardia to the ventricles at a potentially lethal rate. Under these circumstances, physicians should use amiodarone, propranolol, or cardioversion as safer alternatives. Consultation with the cardiologist and initiation of cardioversion should also be considered to prevent a thromboembolic complication before conversion of either of these atrial dysrhythmias in the hemodynamically stable patient believed to have the rhythm disorder within 48 hours prior of presentation.

Ventricular Tachycardia. Ventricular tachycardia is not a common dysrhythmia in children. The majority of children with ventricular tachycardia have an underlying condition, such as post–cardiac surgery status, myocarditis, prolonged QT syndrome, drug or toxin exposures (eg, cyclic antidepressants), or electrolyte abnormalities. The treatment of ventricular tachycardia will depend on hemodynamic status of the patient. Torsades de pointes is a unique type of polymorphic ventricular tachycardia characterized by QRS complexes that change in polarity and amplitude. Prolonged QT syndrome, underlying congenital cardiac defects, hypomagnesemia, and various medications (eg, cyclic antidepressants) have been identified as known causes of torsades de pointes. The treatment of choice is intravenous magnesium at an initial dose of 25 to 50 mg/kg, up to the adult dose of 2 g over 2 minutes. Class IA (ie, propranolol) and class III (ie, amiodarone) antidysrhythmic agents are contraindicated in the treatment of torsades de pointes because these antidysrhythmic agents are capable of prolonging the QT interval, which could then precipitate the degeneration of the torsades de pointes into a lethal rhythm.

Pulseless Rhythms

Ventricular Fibrillation and Pulseless Ventricular Tachycardia. Ventricular fibrillation and pulseless ventricular tachycardia account for approximately 9% to 10% of out-of-hospital cardiac arrest cases in which a terminal rhythm was recorded. The survival rate for out-of-hospital ventricular fibrillation and pulseless ventricular tachycardia can be as high as 30%, whereas the survival rate from asystolic cardiac arrest is less than 1%. In a study of in-hospital cardiac arrests, a shockable rhythm was present during some point of the resuscitation in 25% of children. The survival rate of children who initially exhibited shockable rhythms was higher than for children with nonshockable rhythms. The use of automated external defibrillators (AEDs) is now acceptable in all age ranges, including infants and children. Pediatric pads (attenuating pads) should be used whenever possible for children 1 year to 8 years old (or less than 25 kg). In infants younger than 1 year, manual defibrillation is preferred. If a manual defibrillator is unavailable or its use is delayed, an AED with a pediatric attenuator may be used; if neither is available, an AED without a dose attenuator may be used.

Asystole and Pulseless Electrical Activity. Asystole is the most common rhythm found in out-of-hospital cardiac arrest in children and is associated with a less than 1% chance of survival. The key to survival from any pulseless electrical activity rhythm is the rapid identification and treatment of the underlying cause. The causes of pulseless electrical activity can be remembered by the six Hs and five Ts: hypovolemia, hypoxia, hydrogen ion (acidosis), hypokalemia/hyperkalemia, hypoglycemia, and hypothermia; and toxins, tamponade, tension pneumothorax, thrombosis (pulmonary or coronary artery), and trauma. The most common cause of pulseless electrical activity in children is profound hypovolemia. As such, an intravenous fluid bolus should always be considered as a therapeutic option during the treatment of pulseless electrical activity.

Special Resuscitation Situations in Children

Children with single-ventricle physiology (eg, hypoplastic left heart syndrome and double-outlet right ventricle physiology) after a palliative shunting procedure should be given standard resuscitation care. Heparin may be used in the pre-arrest or arrest of infants with a systemic–to–pulmonary artery shunt or right ventricle–to–pulmonary artery shunt to halt thrombus propagation in this low circulatory flow state. A target oxyhemoglobin saturation (SpO₂) of approximately 80% is preferred in these children. End-tidal carbon dioxide readings after resuscitation may lag behind as varying pulmonary blood flow changes that do not necessarily reflect cardiac output. The goal is to provide adequate preload with judicious fluids to balance systemic and pulmonary blood flow. If available, extracorporeal membrane oxygenation should be considered in these patients.

Children with a history of pulmonary hypertension should also receive standard resuscitation management. Preload should be optimized with isotonic saline boluses. Inhaled nitric oxide in the ICU may be given to reduce PVR. Early contact with the child’s cardiologist and cardiothoracic surgeon is instrumental in the postresuscitative care of children with CHD.

Bacterial Endocarditis

Perspective

Bacterial endocarditis involves an infection of the endothelial surfaces of the heart with a propensity for the valves. The incidence of bacterial endocarditis in children may be increasing slightly because of the many advances in surgical technology that are now allowing many children with very complex congenital heart lesions to survive. Children with indwelling intravascular lines with or without underlying CHD are also at risk for development of bacterial endocarditis. Although bacterial endocarditis most commonly occurs in children with an underlying CHD or an acquired cardiac lesion (eg, acute rheumatic valvular heart disease), it can also occur in patients with no underlying anatomic defects of the valves or endocardium. Factors that predispose children with underlying anatomic cardiac defects to bacterial endocarditis include dental procedures and other surgical procedures involving the respiratory, gastrointestinal, or genitourinary tracts. Those cardiac lesions with a more turbulent blood flow or a higher flow velocity are more prone to development of bacterial endocarditis secondary to a greater risk of endothelial surface damage, which then increases the risk of platelet deposition and vegetation formation. Cardiac lesions that carry this higher risk include VSD, aortic valvular stenosis, tetralogy of Fallot, single-ventricle states, bicuspid aortic valves, prosthetic valves, and postoperative systemic-to-pulmonary shunts. Isolated secundum ASD carry a much lower risk for bacterial endocarditis because the shunt flow through the ASD is typically of a much lower velocity.

Clinical Features and Diagnostic Strategies

The early clinical manifestations of bacterial endocarditis may be nonspecific. The child may simply present with only fever and tachycardia. However, bacterial endocarditis should be suspected...
in any child with an anatomic cardiac defect who presents with an unexplained fever. This diagnosis should always be considered in any child with a known CHD or an acquired cardiac lesion who presents with any of the conditions listed in Box 170.11. A new heart murmur is present in less than 50% of the bacterial endocarditis cases.\textsuperscript{4,5} Common presenting signs are fever (99%), petechiae (21%), changing murmur (21%), dental caries (14%), and hepatosplenomegaly (14%). Less common signs are CHF (9%), splinter hemorrhages (5%), Roth’s spots (5%), and Osler’s nodes (4%).

In addition to vigilance for the diagnosis of infective endocarditis—especially in children with CHD—the emergency clinician should be aware of the indications for prophylaxis. The AHA in conjunction with the American Academy of Pediatrics (AAP) and the Infectious Diseases Society of America has published revised guidelines for the prevention of infective endocarditis.\textsuperscript{4,5} The changes simplify and greatly narrow the recommendations to provide prophylaxis for only the higher risk patients and procedures (Box 170.12). For those children for whom prophylaxis is recommended, the indications are (1) all dental procedures and (2) any manipulation or perforation of the gingival or oral mucosa. Antibiotic prophylaxis for infective endocarditis is no longer recommended for gastrointestinal and genitourinary procedures (Box 170.13). The committee found that it is still reasonable to give prophylaxis for procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients (Table 170.7).\textsuperscript{4,5}

Diagnostic studies for a child with suspected bacterial endocarditis include a complete blood cell count, C-reactive protein (CRP) assessment, measurement of erythrocyte sedimentation rate (ESR), three blood cultures, chest radiography, and electrocardiography.\textsuperscript{5-8} Cultures from scrapings of cutaneous emboli can also aid in the diagnosis. Although the definitive diagnostic study is the echocardiogram, it is only 80% sensitive in detecting the nidus of infection on the endocardium or valves. Streptococcus viridans and Staphylococcus aureus are the two most common offending organisms recovered from the blood cultures of children with bacterial endocarditis. Studies have shown that in children with CHD, 60% of the cases caused by staphylococcal species are methicillin resistant and associated with increased risk of mortality.

Management

Antibiotics should be started immediately after blood culture samples have been obtained. Although the choice of intravenous antibiotics depends on the suspected source of seeding and the child’s immune status, a commonly recommended regimen includes an aminoglycoside plus a penicillinase-resistant penicillin, such as oxacillin. If methicillin-resistant staphylococcus is suspected, vancomycin should also be included in the initial empirical antibiotic regimen.\textsuperscript{49}

An increase in antibiotic resistance to the three major causes of bacterial endocarditis—streptococcii, staphylococci, and enterococci—has increased the mortality rate of bacterial endocarditis, now at 25% to 40%.\textsuperscript{35} Complications of bacterial endocarditis include systemic septic emboli, pulmonary emboli, central nervous system emboli with resultant neurologic deficits, dysrhythmias, CHF, myocarditis, myocardial abscesses, and valvular obstruction and destruction. Despite appropriate antibiotic treatment, surgical intervention to remove septic vegetations or valve replacement is sometimes necessary.

Myocarditis

Myocarditis is an inflammatory condition of the myocardium with various infectious and noninfectious origins. In the United States, the most common cause is viral; coxsackievirus B and enteroviruses account for the majority of cases. Other viral causes

**BOX 170.11**

Clinical Conditions in Which Bacterial Endocarditis Should Be Suspected in a Child With an Underlying Anatomic Cardiac Defect

- Fever of unknown etiology
- A change in the quality of the preexisting heart murmur or the presence of a new heart murmur
- Development of a neurologic deficit (secondary to central nervous system emboli)
- New-onset microscopic hematuria
- Splenomegaly
- Petechiae
- Splinter hemorrhages involving the conjunctiva, nail beds, palms, or soles
- Myalgias

**BOX 170.12**

Cardiac Conditions for Which Endocarditis Prophylaxis Is Recommended

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD)*
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device during the first 6 months after the procedure\textsuperscript{1}
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device (which inhibit endothelialization)
- Cardiac transplantation recipients who have cardiac valvulopathy

**BOX 170.13**

Procedures for Which Endocarditis Prophylaxis Is Recommended

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa* Consider prophylaxis for incisional procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients

*Except for those conditions above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

\textsuperscript{1}Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.
include echoviruses, influenza A and B viruses, adenovirus, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, and hepatitis B virus. Bacterial causes include Corynebacterium diphtheriae, Streptococcus pyogenes, S. aureus, Mycoplasma pneumoniae, Borrelia burgdorferi, and meningococcus. Noninfectious causes include Kawasaki disease, acute rheumatic fever (ARF), collagen vascular disorders (eg, systemic lupus erythematosus), toxins (eg, cocaine and doxorubicin), endocrine disorders (eg, hyperthyroidism), and drug-induced hypersensitivity (eg, penicillins, sulfonamides, phenytoin, carbamazepine).

**Clinical Features**

Viral myocarditis usually has a gradual onset with preceding upper respiratory tract infection. Providers should consider myocarditis in infants and children with symptoms out of proportion to the typical course of a benign cause, such as a viral syndrome. In mild cases, the only sign of myocarditis may be tachycardia. Tachycardia that is disproportionate to the degree of fever should alert the emergency clinician to the possibility of myocarditis. Other presenting signs and symptoms include fever, myalgias, fatigue, tachypnea, wheezing, abdominal pain, and chest pain. More severe cases of myocarditis can even have signs and symptoms of acute CHF and various dysrhythmias. Children who present in CHF with poor perfusion (such as, lethargy, delayed capillary refill, poor urine output, or hypotension) will likely require inotropic support, positive pressure ventilation, or diuretics. The use of beta-blockers is contraindicated, and the routine use of immunosuppressive agents remains controversial. Although the majority of children with acute viral myocarditis make a full recovery, a few patients will progress to dilated cardiomyopathy, which is characterized by dilated ventricles and impaired systolic contractility.

**Pericarditis**

Pericarditis is an inflammatory process within the pericardial sac that may not be associated with a pericardial effusion. In the majority of cases, pericarditis in children is self-limited and follows a benign clinical course. A sudden increase or a large amount of fluid within this pericardial sac can cause a tamponade-induced decrease in stroke volume, resulting in diminished cardiac output and hypotension.

The most common causes of pericarditis include bacterial and viral infections; other causes are ARF, systemic lupus erythematosus, uremia, post-pericardiotomy syndrome, leukemia, lymphoma, and tuberculosis. Approximately 30% of pericarditis cases are due to bacteria, such as pneumococcus, S. aureus, meningococcus, and Haemophilus influenzae. Approximately 30% of the purulent bacterial pericarditis cases occur in children younger than 6 years old. Viral causes are most common, but a specific viral pathogen is recovered in only 20% to 30% of cases. Viral causes include coxsackieviruses, echoviruses, adenovirus, Epstein-Barr virus, and influenza viruses.

**Diagnostic Testing and Management**

The evaluation and management of the child with myocarditis depend on the suspected cause and presenting signs and symptoms. Blood cultures and viral titers should be considered in infectious and post-infectious cases. Appropriate antibiotics should be initiated immediately in cases with suspected bacterial origin. The chest radiograph may be normal in very mild cases, but cardiomegaly will be evident in more advanced cases. The electrocardiographic findings are usually nonspecific and can include low-voltage, nonspecific ST segment abnormalities, T wave inversions, atrioventricular block, and various other dysrhythmias. Creatine kinase-MB, cTnT, cTnl, CRP, and ESR may be elevated.

Bedside echocardiography can evaluate for effusion, tamponade, and global function. The goal of treatment is to maintain adequate cardiac output and to control any associated dysrhythmias. Children who present in CHF with poor perfusion (such as, lethargy, delayed capillary refill, poor urine output, or hypotension) will likely require inotropic support, positive pressure ventilation, or diuretics. The use of beta-blockers is contraindicated, and the routine use of immunosuppressive agents remains controversial. Although the majority of children with acute viral myocarditis make a full recovery, a few patients will progress to dilated cardiomyopathy, which is characterized by dilated ventricles and impaired systolic contractility.
The classic electrocardiographic changes associated with pericarditis evolve through four phases (Fig. 170.14). During the initial phase, there is diffuse ST segment elevation secondary to subepicardial inflammation; PR segment depression may also be seen. During the second phase, the previously elevated ST segments begin to return to isoelectric baseline, and the T wave amplitudes begin to decrease with flattening of the T waves. During the third phase, although the ST segments are now back to isoelectric baseline, the T waves are inverted. The fourth and final phase demonstrates complete resolution of the ST segment and T wave abnormalities. Diminished electrocardiographic voltages in all leads can also occur if there is a significant amount of fluid accumulated within the pericardial sac.

The diagnostic procedure of choice in any patient with suspected pericarditis is the echocardiogram; this study will confirm both the presence and the amount of accumulated fluid within the pericardial sac. Although echocardiography cannot accurately quantify the exact amount of fluid that has accumulated within the pericardial space, the presence of an anterior and posterior fluid collection is suggestive of a large collection.

Tachypnea, neck vein distention, pulsus paradoxus, hepatomegaly, lower extremity edema, and thready distal pulses if heart failure is present. Cardiac auscultatory findings can include a harsh-sounding friction rub or diminished or muffled heart tones if there is a significant amount of fluid within the pericardial sac. The pericardial friction rub, if present, is best heard when the patient sits up or leans forward. This friction rub of pericarditis can be distinguished from a pleural friction rub by having the patient hold his or her breath during auscultation. The friction rub of pericarditis will remain present during breath-holding; the pleural friction rub will no longer be heard while the patient holds the breath.

The chest radiograph in a child with pericarditis may not reveal an enlarged cardiac silhouette. If there is a large collection of fluid within the pericardial sac, the heart shadow on the chest radiograph will resemble a “water bottle” silhouette. Approximately 50% of pericarditis cases have some associated pleural effusion.62,63

The classic electrocardiographic findings of viral pericarditis include diffuse ST segment elevation and diffuse T wave inversions. The classic electrocardiographic changes associated with pericarditis evolve through four phases (Fig. 170.14). During the initial phase, there is diffuse ST segment elevation secondary to subepicardial inflammation; PR segment depression may also be seen. During the second phase, the previously elevated ST segments begin to return to isoelectric baseline, and the T wave amplitudes begin to decrease with flattening of the T waves. During the third phase, although the ST segments are now back to isoelectric baseline, the T waves are inverted. The fourth and final phase demonstrates complete resolution of the ST segment and T wave abnormalities. Diminished electrocardiographic voltages in all leads can also occur if there is a significant amount of fluid accumulated within the pericardial sac.
Management

The management of a child with pericarditis depends on both the suspected cause, severity of symptoms, and amount of fluid that has accumulated within the pericardial space. Patients with fever, respiratory distress, or signs of CHF should be admitted and an echocardiogram emergently performed. An emergency pericardiocentesis is required in those patients with signs of acute cardiac tamponade. Any fluid that is aspirated from the pericardial space should be sent for routine cell counts, Gram’s stain, and cultures. Antiinflammatory agents and appropriate antibiotics should be initiated on the basis of the suspected cause. Steroids are reserved for refractory cases that are not responsive to these agents and should be considered only after an infectious etiology is ruled out.64-65

Kawasaki Disease

Kawasaki disease, originally described as mucocutaneous lymph node syndrome by Dr. Tomisaku Kawasaki in 1967, has emerged as a significant cause of acquired cardiac disease in children in the United States. An estimated 3000 to 5000 cases of Kawasaki disease are diagnosed annually in the United States. Up to 20% of untreated children have some degree of coronary artery abnormalities.66,67 This febrile, exanthematous, multisystem vasculitis is seen most commonly in children younger than 5 years old, with a male-to-female ratio of 1.5:1. Although the exact cause of this vasculitis of small- and medium-sized vessels remains unknown, early clinical recognition and initiation of high-dose aspirin and intravenous immune globulin (IVIG) improve the morbidity and mortality rates of Kawasaki disease in children.

Clinical Features

In addition to fever, the physical examination of a child with Kawasaki disease may reveal the typical findings as listed in Box 170.14 and illustrated in Figure 170.15. The classic features of Kawasaki disease may be manifested simultaneously or in series of days; a careful history and physical examination may elucidate the need for further testing. In addition, very young children may not have a classic presentation and require further investigation. All children with suspected Kawasaki disease, with either classic or incomplete features, should undergo echocardiography for detection of the presence and degree of coronary aneurysm.68

Incomplete Kawasaki Disease

The classic presentation of Kawasaki disease is a clinical diagnosis of four or more of the five criteria in a child who is febrile 5 days or more. However, these strict criteria may miss a substantial number of children who present with incomplete Kawasaki disease. Any child may have an incomplete presentation, but this is mostly seen in infants younger than 6 months old.

The AHA’s Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease has published consensus guidelines on the approach to incomplete Kawasaki disease.66,67 The more inclusive criteria recommend that in a child who is febrile 5 days or more, the presence of two or three criteria should prompt further testing. A CRP of 3 mg/dL or more or an ESR of 40 mm/hr or more should prompt further laboratory investigations; children with elevated inflammatory markers should be empirically treated (Box 170.15). During their hospital stay, children should receive an echocardiogram to assess for coronary aneurysms.

Children with a CRP of less than 3 mg/dL and an ESR of less than 40 mm/hr may be observed daily and reassessed without treatment; serial ESR and CRP should be obtained daily on an outpatient basis. Infants 6 months of age or younger are more likely to present with incomplete Kawasaki disease and are more susceptible to giant coronary artery aneurysm formation. For this reason, irrespective of general well appearance or lack of clinical findings, infants 6 months of age or younger with fever lasting for 7 days or more should undergo supplemental laboratory testing and undergo echocardiogram when inflammatory markers are abnormal. This underscores the current limits of diagnosis of Kawasaki disease, as well as the obligation to prevent the disastrous sequelae of aneurysmal development.

Differential Diagnoses

Measles can mimic Kawasaki disease (ie, a febrile illness with red eyes, a rash, and erythema of the oropharynx). The measles rash classically begins on the head and face and progresses caudally. The rash of Kawasaki disease typically begins on the trunk and then spreads to the face and extremities; it may be polymorphous, but not bullous or vesicular.

The palmar lesions of measles are discrete macular lesions (see Fig. 170.15, F), whereas the palmar finding in children with Kawasaki disease is diffuse erythema, which may later desquamate (see Fig. 170.15, C).

**Box 170.14**

**Diagnostic Criteria for Kawasaki Disease**

- Fever for 5 days or more
- At least four of the five following physical examination findings:
  1. Bilateral, nonexudative bulbar conjunctival injection (bilateral scleral injection with peribulbar sparing)
  2. Oropharyngeal mucous membrane changes (pharyngeal erythema, red and cracked lips, and a strawberry tongue)
  3. Cervical lymphadenopathy (with at least one node >1.5 cm in diameter)
  4. Peripheral extremity changes (diffuse erythema and swelling of the hands and feet during the acute phase or periungual desquamation during the convalescent phase of the illness); this diffuse palmar erythema seen in Kawasaki disease is in contrast to the discrete macular lesions of various viral illnesses (eg, measles) that can sometimes be seen on the palms and soles
  5. A polymorphous generalized rash (non-vesicular and nonbullous); there is no specific rash that is pathognomonic for Kawasaki disease
- In a child with four or more criteria, the diagnosis may be made on day 4 of the fever.

**Box 170.15**

**Supplemental Laboratory Criteria for Kawasaki Disease**

- Albumin ≤3 g/dL
- Anemia for age
- Platelet count of ≥450,000/mm³
- White blood cell (WBC) count ≥15,000 mm³
- Elevation of alanine aminotransferase
- Sterile pyuria of ≥10 WBCs per high-power field

Streptococcal disease, including pharyngitis and scarlet fever, can be confused with Kawasaki disease, but conjunctivitis and swelling of the hands and feet are unusual for streptococcal disease. Other infectious or autoimmune causes that mimic Kawasaki disease include Rocky Mountain spotted fever, leptospirosis, Stevens-Johnson syndrome, and juvenile rheumatoid arthritis.66,67

There are many imitators of Kawasaki disease. Conversely, this systemic vasculitis can affect any organ system and thus be misleading. For example, Kawasaki disease can present with nausea, vomiting, and abdominal pain in a febrile child, which may be mistaken for a surgical abdomen. In addition, a febrile irritable child with Kawasaki disease may have a cerebrospinal fluid pleocytosis and be misdiagnosed with viral meningitis. For this reason, Kawasaki disease should be included in the differential diagnosis of any child with several days of fever, rash, and non-purulent conjunctivitis to avoid the pitfall of early diagnostic closure.
Clinical Course

Kawasaki disease is postulated to be caused by an infectious agent that enters the respiratory tract and initiates an oligoclonal immunoglobulin A response, which activates lymphocytes, cytokines, and proteinases that weaken vessel walls and predispose the entire circulation to aneurysms. Approximately 25% of patients have mild diffuse myocardial inflammation. This occurs during the acute febrile period and is characterized by tachycardia, a gallop, and nonspecific ST-T wave changes. Up to 5% of the children also exhibit some degree of CHF during this acute phase of their illness. This carditis usually resolves when the fever resolves. Pericardial effusions also occur in up to 20% to 40% of cases. Mild mitral and aortic regurgitation is also seen in 1% to 2% of untreated cases on echocardiographic examinations. This phase of the disease is mild and self-resolving.

Recognition of Kawasaki disease allows for prompt treatment, to prevent cardiac complications; these complications usually peak 2 to 4 weeks from the onset of the illness and are seen in 15% to 25% of untreated patients. These coronary aneurysms can lead to myocardial infarction, thrombosis, rupture, or dysrhythmias. Significant risk factors for coronary aneurysmal formation include male gender, age younger than 1 year old, or older than 8 years old, prolonged febrile period longer than 10 to 14 days, early myocarditis, anemia (hemoglobin <10 g/dL), white blood cell count more than 30 × 10^9/hpf, increased band count, elevated ESR, elevated CRP level, low serum albumin levels, aneurysms involving other arteries (renal, axillary, or iliac), and giant coronary aneurysms (>8 mm in diameter). Death from Kawasaki disease is primarily due to myocardial infarction secondary to coronary artery occlusion. Giant coronary artery aneurysmal rupture is rare. Although most of the fatalities of Kawasaki disease occur within 6 weeks from the onset of the illness, sudden death can occur many years after the illness. Prompt recognition and treatment have decreased this mortality rate from 2% to less than 0.01%.67

Management

The main goal of treatment during the acute febrile phase of Kawasaki disease is to provide supportive care and to decrease the inflammation of the myocardium and coronary arteries. IVIG and high-dose aspirin have an additive effect and—when initiated within 10 days from the onset of the illness—can substantially decrease the progression to coronary artery dilation and aneurysm formation compared with aspirin therapy alone.68 The combination results in a more rapid resolution of fever and the other indicators of acute inflammation.68 However, despite prompt treatment with IVIG and high-dose aspirin, 2% to 4% of children still have coronary artery abnormalities.69

The current IVIG regimen involves an infusion of 2 g/kg over 10 to 12 hours. Side effects of IVIG include hypotension, nausea, vomiting, headache, and seizures. Close cardiac monitoring during the IVIG infusion is recommended. The 5% to 10% of children who receive IVIG and experience a persistent or recurrent fever after the initial dose of IVIG may be given a second infusion at the same dose. Approximately two-thirds of children who fail to respond to the initial dose of IVIG will improve with the second infusion. Aspirin is initiated at 80 to 100 mg/kg/day orally divided into an every-6-hour dosing regimen until the child is afebrile for 48 to 72 hours. This dose is then decreased to 3 to 5 mg/kg orally each day until the laboratory study results return to normal, which typically occurs 6 to 8 weeks after the onset of the disease.68-70

Aspirin therapy is continued beyond this period only in those children in whom coronary artery abnormalities are present. Ibuprofen can antagonize the antiplatelet effects of aspirin and should be avoided during treatment.

The follow-up of children with Kawasaki disease depends on the degree and presence of carditis and coronary artery abnormalities detected on the initial echocardiogram. Other imaging modalities used to follow aneurysmal parameters include electron-beam computed tomography, coronary magnetic resonance angiography, and computed tomography. Those children with more severe cardiac abnormalities should have close follow-up by a cardiologist experienced in Kawasaki disease. Prompt diagnosis and treatment leads to rapid symptomatic improvement in 90% of cases and prevents coronary aneurysm formation in 95%.

Acute Rheumatic Fever

ARF, one of the most common causes of acquired heart disease in children, is the result of a delayed immune reaction to a group A streptococcal infection. In the United States, ARF most commonly occurs in children 5 to 15 years old, with an attack rate of 0.3% in children with an untreated streptococcal infection. Although this disease affects multiple organ systems, carditis is the most serious complication.

Clinical Features and Diagnostic Testing

The diagnosis of ARF is based on the Jones criteria (Box 170.16). In addition, there must also be evidence of an antecedent streptococcal infection, which can be documented by a positive throat culture, a positive rapid streptococcal antigen test, or an elevated antistreptolysin O (ASO) titer. The ASO titer begins to rise 1 to 3 weeks after streptococcal infection, peaks at 3 to 5 weeks, and reliably falls to baseline after 6 months. The streptozyme test is not as reliable and therefore should not be used as a definitive test for evidence of an antecedent group A streptococcal infection.71 The diagnosis of ARF is made in a patient with a documented antecedent streptococcal infection who exhibits either two major criteria or one major plus two minor criteria.72

The most common presenting major criterion is the migratory polyarthritis, which commonly involves the larger joints of the

---

**Jones Criteria for the Diagnosis of Acute Rheumatic Fever**

The diagnosis of acute rheumatic fever (ARF) is based on the documentation of an antecedent streptococcal infection and (1) two major criteria or (2) one major criterion plus two minor criteria.

**MAJOR CRITERIA**
- Carditis
- Migratory polyarthritis
- Erythema marginatum
- Subcutaneous nodules
- Chorea

**MINOR CRITERIA**

**Clinical findings:**
- Fever
- Arthralgia

**Laboratory findings:**
- Elevated C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)
- Prolonged PR interval

Supporting evidence of an antecedent group A streptococcal infection with either of the following:
- A positive throat culture or rapid streptococcal antigen test result
- An elevated antistreptolysin O (ASO) titer
extremities, as well as the smaller tarsal joints in the foot and the smaller carpal joints in the hand. The carditis of ARF most commonly involves valvulitis of the mitral and aortic valves, which clinically is manifested as occult mitral or aortic insufficiency. The murmur of mitral insufficiency is characterized as a holosystolic murmur best heard over the apex with radiation to the axilla. The murmur of aortic insufficiency is characterized as a diastolic murmur that is best heard over the base of the heart. Innocent murmurs that are normally exacerbated with fever can be mistaken for the murmurs of mitral or aortic insufficiency.

Other cardiac manifestations of ARF include CHF, pericarditis, and various degrees of heart block. The two dermatologic major criteria (erythema marginatum and subcutaneous nodules) and chorea occur less commonly than the migratory polyarthritis and carditis. Chorea may occur as the only manifestation of ARF. If arthritis is used as a major component, arthralgia cannot be used as a minor component to make the diagnosis. Likewise, if carditis is used as a major component, a prolonged PR interval cannot be used as a minor component.

In addition to the ECG, CRP or ESR levels, and documentation of an antecedent streptococcal infection, the diagnostic evaluation of ARF should also include a chest radiograph, as well as an echocardiogram to evaluate the degree of cardiac involvement.

### Differential Diagnoses

The differential diagnosis of ARF includes myocarditis, bacterial endocarditis, Lyme disease, systemic lupus erythematosus, juvenile rheumatoid arthritis, serum sickness, and septic arthritis.

### Management

The acute management of ARF should focus on stabilization and treatment of any of the symptomatic cardiac manifestations of the illness, such as CHF or tamponade due to a pericardial effusion. Treatment should also include appropriate antibiotic therapy to eradicate the streptococcal infection, bed rest, and anti-inflammatory agents for arthritis. Steroids should be used in the treatment of carditis only under direction of a cardiologist. Monthly injections of benzathine penicillin G provide prophylaxis against recurrent attacks; alternative regimens include oral penicillin administered twice daily and, for penicillin-allergic patients, twice daily oral erythromycin. Prophylaxis is required until 18 years of age but can be continued for life, depending on the degree of cardiac involvement and risk of recurrence.

### Cardiac Causes of Sudden Death in Young Athletes

In a large registry study of 1866 sudden deaths in young athletes, 1048 (56%) were due to cardiovascular disease and 416 (22%) were due to direct blunt trauma. The most common cardiovascular cause of sudden death in the athlete is hypertrophic cardiomyopathy, accounting for up to 36% of the cardiovascular-related cases (Box 170.17).

### Specific Disorders

**Congenital Coronary Artery Anomalies.** An additional 24% of the cases of sudden death are due to various anomalies of the coronary arteries. Congenital coronary artery anomalies are difficult to detect from a clinical standpoint, but 37% of those individuals who died of congenital coronary artery anomalies exhibited previous symptoms of exercise-induced syncope or chest pain. The exact pathophysiologic mechanism of sudden death in individuals with congenital coronary anomalies is unknown. Although there are a variety of congenital coronary artery anomalies, the most common potentially lethal lesion is the anomalous left coronary artery, in which the left main and right coronary arteries both arise from the right sinus of Valsalva. Individuals with this particular anomaly have a 46% incidence of sudden death, with more than 85% of the known cases of sudden death occurring during exercise. Congenital coronary artery hypoplasia is another uncommon cause of exercise-induced sudden death. Any athlete with exertional syncope or chest pain should be evaluated by a cardiologist for the possibility of a congenital coronary artery anomaly. If an anomaly is detected and surgically corrected, the athlete may resume full activity and participation in competitive sports.

**Marfan Syndrome.** Individuals with Marfan syndrome should be evaluated for potential cardiac abnormalities before being allowed to participate in competitive sports. Clinical manifestations of the disease include tall and slender habitus, striae atrophicae, disproportionately long extremities compared with the trunk, scoliosis, pectus excavatum or carinatum, and lens dislocation. Approximately 50% of patients with Marfan syndrome have cardiac manifestations, such as mitral valve prolapse or aortic dilation. The most serious cardiac complication of Marfan syndrome is the progressive dilation of the aorta with the potential risk of aortic rupture, which most commonly involves the descending portion of the aorta. Therefore, patients with Marfan syndrome should be prohibited from participation in contact sports. Those individuals who are known to have aortic dilation should also be prohibited from participation in any competitive sports regardless of the degree of contact involved. All patients with Marfan syndrome with or without cardiac involvement on their initial evaluation should be observed by a cardiologist with serial imaging studies of the aorta by echocardiography, magnetic resonance imaging, or computed tomography.

**Hypertrophic Cardiomyopathy.** Obstructive hypertrophic cardiomyopathy involves a thickened muscular intraventricular septum that bulges into the left ventricle and impedes forward flow, causing chest pain, shortness of breath, pre-syncope, or syncope. The nonobstructive form, which occurs when the thickened septum does not block forward flow, occurs in only 0.2% of the general population, yet it is the single most common cardiac cause of sudden death in the young athlete. Sudden death in previously asymptomatic individuals with hypertrophic cardiomyopathy occurs during moderate or severe physical exertion. The proposed pathophysiologic mechanism of sudden death during exertion in these individuals is thought to be a transient decrease of blood flow out through the aorta or dysrythmia originating from the hypertrophied ventricular myocardium.

</table>
Hypertrophic cardiomyopathy is a familial disease, inherited in an autosomal dominant fashion with variable penetrance. The hypertrophy of the left ventricle in this condition is idiopathic in nature and not due to chronic pressure overload conditions, such as systemic hypertension or aortic stenosis. The systolic left ventricular contractile function is vigorous, but the thickened muscle of the left ventricle is stiff, resulting in impaired ventricular relaxation and high diastolic filling pressures.

Clinical Features. Some individuals with hypertrophic cardiomyopathy have experienced previous “warning” episodes of chest pain, dyspnea, syncope, or palpitations during vigorous activities. A family history of sudden unexplained death in young adults should also alert the clinician to the possibility of hypertrophic cardiomyopathy. The majority of young athletes who die of this condition have the nonobstructive form of hypertrophic cardiomyopathy, and the classic loud systolic ejection murmur that is present with the obstructive form may not be heard during the routine pre-sports physical examination.75,76

If a systolic murmur along the lower left sternal border is heard on the routine screening physical examination of a young athlete, a Valsalva maneuver may help differentiate the murmur of aortic stenosis from the systolic murmur associated with the obstructive form of hypertrophic cardiomyopathy. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. The transient reduction in the size of the left ventricle will increase the degree of obstruction and thus cause an increase in the intensity of the systolic murmur heard with the obstructive form of hypertrophic cardiomyopathy. In contrast to this, the systolic murmur of aortic stenosis will decrease in intensity during a Valsalva maneuver because of the transient reduction of blood flow through the stenotic aortic valve.

Current recommendations for pre-sports screening include a detailed family and personal history of known or suspected heart disease, physical examination, and 12-lead ECG.77 If any suspicion remains, further evaluation (eg, echocardiography, Holter monitoring, other imaging studies) and referral to a cardiologist are indicated.78

Diagnostic Testing. The electrocardiographic findings in individuals with hypertrophic cardiomyopathy typically reveal various degrees of left ventricular hypertrophy and left atrial enlargement. Other electrocardiographic findings include prominent Q waves in the inferolateral leads and diffuse T wave inversions. The most accurate study for the diagnosis of hypertrophic cardiomyopathy is the echocardiogram, which will demonstrate various degrees of left ventricular hypertrophy and involving the ventricular septum in up to 90% of the cases. Patients with echocardiographic evidence of hypertrophic cardiomyopathy should receive serial echocardiographic examinations to monitor progression.79

Management. Beta-blockers are the mainstay of pharmacologic therapy (verapamil is second-line). Beta-blockers exert negative inotropic effects, attenuate adrenergic-induced tachycardia, improve myocardial oxygen supply-and-demand, and improve diastolic filling.78 No pharmacologic therapy has been proven to prevent sudden death. The use of digoxin is contraindicated in patients with hypertrophic cardiomyopathy because its positive inotropic effect may worsen the left ventricular outflow obstruction. Sudden death in patients with hypertrophic cardiomyopathy is thought to be due to exertion-induced ventricular fibrillation or pulseless ventricular tachycardia. Therefore, all individuals diagnosed with hypertrophic cardiomyopathy, as well as those with an equivocal diagnosis of hypertrophic cardiomyopathy should not participate in vigorous activities and competitive sports.75

A transaortic septal myomectomy may be considered for patients with severe symptoms unresponsive to medical therapy. For suboptimal surgical candidates, implantation of a dual-chamber pacemaker may improve symptoms by decreasing the left ventricular outflow tract gradient.

Prolonged QT Syndrome. In 1957, Jervell and Lange-Nielsen first described the association of recurrent syncope, sudden death, and long QT interval in a series of deaf patients. Later, in 1963, Romano reported a similar association of symptoms with long QT intervals in patients with normal hearing. Both the Jervell–Lange–Nielsen and the Romano–Ward syndromes are inherited disorders with variable penetrance, characterized by a prolonged QT interval that has been associated with sudden death. The corrected QT (QTc) interval in normal individuals should not exceed 0.44 second in children or 0.42 second in adolescents. Individuals with QTc intervals longer than 0.55 second have a higher risk of sudden death. Prolongation of the QT interval predisposes the individual to ventricular tachycardia, torsades de pointes, and ventricular fibrillation, which is often initiated by a premature ventricular contraction occurring during the prolonged repolarization phase. In addition to the inherited syndromes of prolonged QT intervals, other causes of prolonged QT intervals include hypocalcemia, hypokalemia, hypomagnesemia, myocarditis, and medications (eg, procainamide, erythromycin, cyclic antidepressants, phenothiazines, quinidine, and organophosphates).

Clinical Features. Symptoms in the young athlete that are suggestive of QT prolongation include exercise-induced palpitations, chest pain, syncope, dizziness, and atypical seizures. The young athlete who has any of these symptoms should be evaluated by a cardiologist, especially if the family history is positive for sudden unexplained death, cardiac problems, syncope, or deafness. Any young athlete who has been diagnosed with a prolonged QT syndrome should be prohibited from participation in competitive sports and vigorous activities. The growing popularity and presence of AEDs in public places and at sporting events can potentially save the lives of those athletes who suddenly collapse because of an underlying prolonged QT syndrome–induced non-perfusing ventricular dysrhythmia.

Management. Treatment of a prolonged QT interval depends on the cause. Underlying metabolic disorders should be corrected, and medications that induce prolongation of the QT interval should be discontinued. Magnesium sulfate is the drug of choice in the treatment of torsades de pointes. Lidocaine is the safest medication for patients with prolonged QT interval–induced ventricular tachycardia or fibrillation. Anti-dysrhythmic agents that can prolong the QT interval, such as procainamide and amiodarone, should be avoided. Beta-blockers have been used to prevent sudden ventricular dysrhythmias in those patients with the familial forms of QT prolongation. Adjunctive treatment in these selected patients also includes the insertion of pacemakers or internal defibrillators.

Commotio Cordis. Commotio cordis occurs after a high-impact trauma to the chest, as in a high-speed motor vehicle collision or a baseball to the sternum. The impact occurs during the vulnerable repolarization period of the cardiac cycle, mechanically inducing ventricular fibrillation. This phenomenon most commonly occurs in children between 5 and 15 years old with no known predisposing cardiac conditions.79,80 Although commotio cordis most commonly occurs in baseball, it has also been reported to occur in ice hockey, lacrosse, softball, and fist fights.80 The majority of patients who sustain commotio cordis do not survive unless rapidly treated with defibrillation. If an AED is not immediately available and the patient is completely unresponsive with no pulse after sustaining a direct blow to the chest, a chest thump during CPR should be attempted.
The possibility of a congenital heart defect should be considered in an infant who presents with central cyanosis that does not respond to 100% supplemental oxygen (hyperoxia challenge).

Neonates with ductal-dependent cardiac lesions typically present within the first 2 to 3 weeks of life with either acute cyanosis or shock. Initiation of a prostaglandin E1 (PGE1) infusion (0.05 to 0.1 µg/kg/min) will be lifesaving in these neonates.

Treatment of a hypoxic tet spell first includes the placement of an infant in the knee-to-chest position or of an older child in a squatting position to increase systemic vascular resistance (SVR) and the provision of supplemental oxygen. Sedative agents can be used to decrease hyperpnea. Various medications can be used as adjunctive treatment to increase the SVR and thereby decrease the degree of right-to-left shunting across the ventricular septal defect (VSD).

Prompt recognition of the clinical findings and symptoms of Kawasaki disease along with the rapid initiation of high-dose aspirin and intravenous immune globulin (IVIG) infusion can prevent the formation of coronary aneurysms.

Acute bacterial endocarditis should always be considered in a child with a known congenital heart defect or an acquired cardiac defect who presents with fever of unknown origin, acute neurologic deficits, new-onset microscopic hematuria, myalgias, splenomegaly, petechiae, or other signs of systemic embolization.

Oxygen, positive pressure ventilation (noninvasive or invasive), diuretics, and possibly inotropes are the main emergency department (ED) treatment of infants and children who present with congestive heart failure (CHF).

If vagal maneuvers fail to convert stable paroxysmal supraventricular tachycardia in children, rapid adenosine administration (0.1 mg/kg for the first dose, followed by 0.2 mg/kg on repeated doses) is the treatment of choice. Verapamil should be avoided in children younger than 1 year old because of its profound hypotensive effects.

Consider the use of lidocaine instead of amiodarone in cases of ventricular fibrillation or ventricular tachycardia due to medications (eg, cyclic antidepressants) or toxins that prolong the QT interval.

Young athletes with a positive family history of sudden unexplained death or exertion-induced symptoms (such as, chest pain, dyspnea, palpitations, and syncope) should be evaluated by a cardiologist before their resumption of vigorous activity.

The increased presence of automated external defibrillators (AEDs) in public places and at sporting events can potentially save the lives of more young athletes who suddenly collapse secondary to hypertrophic cardiomyopathy, prolonged QT syndromes, and commotio cordis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

170.1. Which of the following congenital heart diseases (CHDs) requires a patent ductus arteriosus to preserve blood flow from the main pulmonary artery to the systemic circulation?  
A. Pulmonary atresia  
B. Severe aortic stenosis  
C. Tetralogy of Fallot  
D. Transposition of the great vessels  
E. Tricuspid atresia  

**Answer:** B. Pulmonary atresia, tetralogy of Fallot, transposition of the great vessels, and tricuspid atresia are also ductal-dependent lesions, but they require a patent ductus arteriosus (PDA) to preserve blood flow from the aorta to the pulmonary circulation.

170.2. Which of the following is considered a cyanotic congenital heart defect (CHD)?  
A. Aortic stenosis  
B. Atrial septal defect (ASD)  
C. Coarctation of the aorta  
D. Tetralogy of Fallot  
E. Ventricular septal defect (VSD)  

**Answer:** D. Aortic stenosis, ASD, coarctation of the aorta, and VSD are all considered acyanotic CHDs. The classic cyanotic CHDs can be remembered by the "five Ts": truncus arteriosus, transposition of the great vessels, tricuspid atresia, tetralogy of Fallot, and total anomalous pulmonary venous return.

170.3. Which of the following increases the systemic vascular resistance (SVR), thus producing a left-to-right shunt through the ventricular septal defect (VSD) associated with tetralogy of Fallot?  
A. Acute hypovolemia  
B. Crying  
C. Defecation  
D. Squatting  
E. Tachycardia  

**Answer:** D. Squatting or knee-to-crotch positions increase the SVR, thus improving the left-to-right shunt. Acute hypovolemia, crying, defecation, and tachycardia are all events that suddenly lower the SVR and produce large left-to-right shunts across the VSD, beginning the vicious cycle of a hypoxic ("tet") spell.

170.4. A 14-year-old girl presents to the emergency department (ED) with altered level of consciousness and trouble breathing. Her vital signs are blood pressure (BP), 72/39 mm Hg; heart rate, 240 beats/min; temperature, 99.6°F; respiratory rate, 60 breaths per minute; and oxygen saturation, 80%. An electrocardiogram (ECG) is performed, which shows supraventricular tachycardia. The patient weights 50 kg. Which of the following is the most appropriate initial treatment?  
A. Adenosine 5 mg IV  
B. Cardioversion with 50 J  
C. Cardioversion with 200 J  
D. Diltiazem 12.5 mg IV  
E. Vagal maneuvers  

**Answer:** B. This patient should be considered unstable supraventricular tachycardia (SVT), with trouble breathing, low O2 saturation, and hypotension. In stable patients, vagal maneuvers may be appropriate to try first, followed by adenosine. Diltiazem may be used for rate control in patients with atrial flutter or atrial fibrillation. Cardioversion is the treatment of choice in patients with hemodynamic instability and SVT. The dose is 0.5 to 1 J/kg.

170.5. What is the most common cause of bradycardia in infants?  
A. Complete heart block  
B. Hypothermia  
C. Hypothyroidism  
D. Hypoxia  
E. Medication induced  

**Answer:** D. Although all of these may cause bradycardia in infants and children, the most common cause is hypoxia.

170.6. A 16-year-old boy presents with complaints of syncope during a basketball game. His mother reports a family history of sudden death in young adults, and you are concerned that the patient may have hypertrophic cardiomyopathy. Which of the following increases the myocardium associated with this condition?  
A. Hand grip  
B. Methoxamine  
C. Passive leg elevation  
D. Squatting  
E. Valsalva
Answer: E. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. This transient reduction will increase the degree of obstruction and thus cause an increase in the intensity of the murmur. Hand grip, methoxamine, passive leg elevation, and squatting will increase return of blood to the heart and therefore decrease the murmur associated with hypertrophic cardiomyopathy.

170.7. A 3-year-old child (15 kg) is in pulseless ventricular tachycardia after being struck in the chest. The patient remains in pulseless ventricular tachycardia despite two doses of defibrillation, one dose of intravenous epinephrine, and high-quality cardiopulmonary resuscitation. The team leader prepares for the third dose of defibrillation to be delivered with a dose of amiodarone. What is the appropriate dose of defibrillation to deliver for this third defibrillation?

A. 15 joules
B. 30 joules
C. 45 joules
D. 150 joules

Answer: D. The first dose of defibrillation should be 2 joules/kg (which would be 30 joules in this 15-kg child). The second dose of defibrillation should be 4 joules/kg (which should be 60 joules in this 15 kg child). The new 2010 pediatric advanced life support (PALS) guidelines recommend that the third and subsequent defibrillation doses be 4 to 10 joules/kg. Therefore the third and subsequent defibrillation doses could be as high as 150 joules. Choice D of 150 joules is within the recommended range of 4 to 10 joules/kg.

In summary:
- First shock: 2 joules/kg
- Second shock: 4 joules/kg
- Subsequent shocks: 4 to 10 joules/kg up to maximum adult dose for the defibrillator

170.8. A 15-year-old boy is sent to the emergency department (ED) from his primary care doctor for further evaluation of “high blood pressure (BP)” recorded in the clinic today on a routine visit. He has no past medical history or symptoms. On examination, his BP is 150/90; when you palpate his radial and femoral pulses simultaneously, there is a marked pulse delay. Which of the following statements regarding this patient’s most likely diagnosis is true?

A. On chest radiograph, the absence of rib-notching rules out the diagnosis.
B. This is an isolated congenital finding; there are no other structural or valvular lesions associated with this condition.
C. The majority of cases involve a lesion distal to the ductus arteriosus.
D. This is a normal variant, and referral back to his primary medical doctor for follow-up is indicated.

Answer: C. This boy has classic findings of asymptomatic coarctation of the aorta (CoA). Dilated collateral vessels are under pressure, causing notching of the posterior ribs, typically seen after 5 years of age. Their absence, however, does not rule out this diagnosis. Up to 30% of patients with CoA have an associated bicuspid aortic valve. Although the coarctation can occur proximal to the insertion of the ductus arteriosus or within the duct itself, the majority (89%) of cases are the postductal type. Weaker or delayed pulses in the lower extremities are common in CoA; BP measurements in all four extremities are indicated if there is any suspicion. This is not a normal variant, and this asymptomatic patient’s evaluation should include an electrocardiogram (ECG; to assess left ventricular hypertrophy) and chest radiograph (to assess cardiomegaly, pulmonary vascular markings). Diagnosing the asymptomatic child with CoA and expediting definitive surgical repair can prevent the complications of severe untreated hypertension, including cardiomyopathy, heart failure, renal failure, and intracranial hemorrhage.

170.9. A 5-month-old girl presents with fever for a week, rash, and fussiness; reportedly yesterday her rash was faint throughout her body and has since resolved. On examination, she is febrile with otherwise reassuring vital signs; she is fussy and has conjunctival injection in both eyes. Her parents think she got sick from their other children. Which of the following statements regarding this patient’s most likely disease is true?

A. If present, other systemic signs (such as, nausea, vomiting, and diarrhea) suggest an alternative diagnosis (such as, acute gastroenteritis).
B. Laboratory investigation in the emergency department (ED) will assist in her risk stratification.
C. Older children are at the highest risk for aneurysm formation.
D. She does not need further testing because she has only one of four criteria at the present.

Answer: B. Kawasaki disease is a systemic vasculitis, and gastrointestinal findings (nausea, vomiting, abdominal pain, diarrhea) and neurologic findings (irritability, positive pleocytosis on lumbar puncture if done) may mislead the clinician. Although she only has one criterion currently, signs of Kawasaki disease may occur in series or simultaneously over the course of the disease. With two or more signs in a child who is febrile for more than 5 days, markers of systemic inflammation (such as, C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]) are indicated to determine the need for further laboratory testing (complete blood count, liver function tests [LFTs], albumin, urinalysis), imaging (echocardiography), or next day follow-up (with repeat laboratory tests). This child is at high risk because infants are more prone to vascular complications (such as, giant aneurysm formation); tragically they are also more likely to present with incomplete Kawasaki disease and may be overlooked. Accordingly, consensus guidelines recommend that all infants younger than 6 months old with fever of 1 week or greater (regardless of other findings) should undergo laboratory testing for markers of inflammation and, if positive, should have an echocardiogram performed emergently.
CHAPTER 171

Gastrointestinal Disorders

Patrick J. Maloney

PRINCIPLES

Gastrointestinal (GI) symptoms are common among pediatric patients presenting to the emergency department (ED). Unfortunately, the signs and symptoms commonly attributed to the GI tract, such as abdominal pain, nausea, anorexia, and vomiting, are often nonspecific and ill-defined because young children lack the social skills and vocabulary to describe and localize their symptoms. As a result, their evaluation and management may be challenging.

Pediatric GI disorders can be divided into different groups on the basis of their unique pathophysiologic mechanisms. Several disorders occur as a normal variant of early neonatal and infant development (eg, neonatal jaundice, gastroesophageal reflux, hypertrophic pyloric stenosis). Others result from congenital malformations (eg, malrotation, Meckel’s diverticulum) or genetic abnormalities (eg, Hirschsprung’s disease). Idiopathic or poorly explained disorders include necrotizing enterocolitis (NEC), intussusception, Henoch-Schönlein purpura (HSP), and inflammatory bowel disease (IBD). The child’s age can also help identify common causes of abdominal pain. Infants, for example, may have disorders such as NEC, hypertrophic pyloric stenosis, or intussusception, whereas older children are more likely to present with appendicitis, pancreatitis, or biliary tract disease (Table 171.1).

SPECIFIC DISORDERS

Neonatal Jaundice

Principles of Disease

Bilirubin is formed by the breakdown of heme-containing proteins, primarily hemoglobin. Unconjugated bilirubin binds to albumin and is carried to the liver, where it is conjugated by glucuronyl transferase and excreted into bile. Hyperbilirubinemia and jaundice in the neonate usually result from a combination of three factors—increased production, decreased clearance and excretion, and increased enterohepatic resorption. Hyperbilirubinemia in the neonatal period is usually unconjugated. Conjugated hyperbilirubinemia, which is always pathologic, is less common.

Nearly every newborn develops an unconjugated serum bilirubin level greater than 1 mg/dL—the normal upper limit in adults—during the first week of life. Jaundice, the yellow discoloration of the skin and sclera, becomes clinically noticeable when the total bilirubin level rises above about 5 mg/dL. Jaundice during the newborn period is usually the result of a benign, self-limited process termed physiologic jaundice of the newborn and occurs in approximately 50% of normal newborns.

At levels greater than approximately 20 to 25 mg/dL, there is an increased risk of bilirubin-induced neurologic dysfunction (BIND). Acute bilirubin encephalopathy (ABE) refers to the early, potentially reversible, signs and symptoms, including somnolence, poor feeding, hypertonia or hypotonia, and a high-pitched cry associated with severe hyperbilirubinemia (≥20 to 25 mg/dL). If untreated, symptoms progress to lethargy, hypertonia, backward arching of the neck (retrocollis) and trunk (opisthotonos), fever, irritability and, ultimately, apnea, seizures, and death. If treated, some or all these symptoms may be reversible. Kernicterus refers to the chronic, long-term neurologic sequelae of BIND. Symptoms include cerebral palsy, sensorineural hearing loss, and gaze abnormalities (usually upward gaze limitations). Management of neonatal jaundice is aimed at preventing the development of kernicterus.

Breast milk jaundice is the second most common cause of neonatal jaundice. The exact pathophysiology is uncertain, but it may be hormonally mediated or related to increased enterohepatic resorption of bilirubin. Other causes of jaundice vary significantly (Tables 171.2 and 171.3); although jaundice in adults is usually the direct result of primary liver disease, infantile jaundice is usually the result of extrahaemolytic causes—genetic, metabolic, infectious, and obstructive.

Risk factors for the development of hyperbilirubinemia in the neonate include prematurity, isoimmune-mediated hemolysis (ABO incompatibility), sepsis, cephalohematomas, dehydration, and inherited abnormalities, such as hereditary spherocytosis and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Unconjugated bilirubin crosses the blood-brain barrier, where it causes cell death.

Clinical Features

Healthy infants are born with normal bilirubin levels that gradually increase to a peak level of 6 mg/dL on the third day of life and then decline to normal levels within 2 weeks. Infants with hyperbilirubinemia usually begin life with similarly low bilirubin levels but exhibit a faster rise in bilirubin levels over the first few days of life. Physiologic jaundice is rarely present within the first 24 hours. Children with breast milk jaundice typically demonstrate the same gradual increase seen with physiologic jaundice, but levels continue to increase and peak at around 10 to 21 days of life. Elevated levels may persist for 3 to 10 weeks before gradually declining.

Toxic levels of bilirubin (dependent on age, but in general >20 mg/dL) may be associated with neurotoxicity, encephalopathy, and the development of kernicterus. Kernicterus is characterized by yellow staining in areas of the basal ganglia. Clinical manifestations of BIND include poor feeding and lethargy and may progress to muscle rigidity, opisthotonos, seizures, and death. Survivors may have chronic, permanent coordination problems, hearing loss, and learning disabilities.

Diagnostic Considerations

Differential Diagnoses. The birth history may reveal a history of trauma that can cause cephalohematomas, or a review of the maternal and infant perinatal records may identify maternal-child blood type and antibody testing. A detailed history of feeding patterns, urine output, and stool appearance may identify poor nutritional intake, poor weight gain, and dehydration. The family history may identify siblings or other relatives with a history of jaundice or genetic or metabolic

disorders. Tables 171.2 and 171.3 present differential considerations for jaundiced infants and children, respectively.

**Diagnostic Testing.** Although physiologic jaundice and breast milk jaundice are most common, pathologic causes and indications for evaluation of hyperbilirubinemia are listed in Box 171.1. Initial testing requires the determination of fractionated levels of total and direct bilirubin. Conjugated (direct) hyperbilirubinemia is always pathologic, resulting from biliary atresia, other biliary obstructive pathology, severe infections, toxins, and inborn errors of metabolism. Evaluation should include a complete blood count (CBC) with a peripheral smear and Coombs test to determine immune-mediated major blood group incompatibility. Diagnostic testing in ill-appearing infants includes finger stick blood glucose level measurement, electrolyte panel, urine assay for reducing substances, serum ammonia levels, and evaluation for infection.

**Management**

The treatment of infants with hyperbilirubinemia centers on the prevention of kernicterus. Guidelines for the use of phototherapy and exchange transfusion, based on age, risk factors for developing BIND, and bilirubin level, have been established and recommended by the American Academy of Pediatrics (Fig. 171.1). Because oral intake stimulates enterohepatic circulation and decreases bilirubin levels, feeding (including breast-feeding) should be continued.

Infants with severely elevated bilirubin levels are at greatest risk for developing BIND. Indications for exchange transfusion include bilirubin level above age-specific threshold recommended by the American Academy of Pediatrics (see Fig. 171.1), failure of phototherapy (ie, the bilirubin level continues to rise despite intensive phototherapy), and jaundiced infants with signs and symptoms of BIND. Exchange transfusions are the most effective and rapid way to remove bilirubin. The procedure is time-consuming and should be performed in a pediatric or neonatal intensive care unit (NICU), where the infant’s hemodynamic status may be closely monitored. A double-volume transfusion (180 to 190 mL/kg packed red blood cells) replaces approximately 85% of an infant’s blood volume and reduces the total bilirubin level by at least 50%. It is performed by serially removing small aliquots of the infant’s blood, typically no more than 5 to 10 mL/kg, and replacing it with a similar volume of packed red blood cells until the total transfusion volume is achieved.

**Disposition**

In general, infants with bilirubin levels greater than 18 to 20 mg/dL require hospital admission and phototherapy. All infants with direct hyperbilirubinemia require admission and evaluation.

**Hypertrophic Pyloric Stenosis**

**Principles of Disease**

Hypertrophic pyloric stenosis is the most common cause of infantile GI obstruction beyond the first month of life. This
The Pediatric Patient

resulting in the classic hypochloremic-hypokalemic metabolic alkalosis.

Clinical Features

Infants classically present at 2 to 6 weeks of chronologic age with gradually progressive vomiting that becomes projectile but remains nonbilious. Early in the disease process, infants remain vigorous, with a ravenous appetite. They rapidly finish an entire feeding, only to regurgitate the entire volume in a projectile fashion. In the later stages of the disease, children may exhibit poor weight gain, clinical dehydration, and malnutrition, along with visible waves of abdominal peristalsis in response to intense contractions against the obstruction.

condition occurs in 1 of every 250 live births, although rates and trends vary significantly by region. Boys are affected at four times the rate of girls. Approximately one-third of cases occur in first-born children. Prematurity and exposure to erythromycin or azithromycin are additional risk factors. Hypertrophic pyloric stenosis tends to have familial patterns, but the exact pattern of inheritance is unclear.

Infants are born with a normal pylorus that enlarges as time progresses. The exact cause is unknown, although hypertrophy seems to be stimulated by feeding. As the pylorus enlarges, progressive gastric outlet obstruction develops, and vomiting ensues. Vomiting causes loss of fluid and hydrogen and chloride ions. As dehydration and electrolyte derangements worsen, the kidney attempts to retain hydrogen ions in exchange for potassium, resulting in the classic hypochloremic-hypokalemic metabolic alkalosis.
Diagnostic Considerations

Diagnostic Testing. Children may have a palpable pylorus in the right epigastrium on abdominal examination, commonly referred to as an olive. Because ultrasound is readily available in most US health centers, pyloric stenosis is generally diagnosed earlier compared to decades ago. As a result, the olive is now palpated in only a minority of infants. Laboratory derangements reflect a state of dehydration and electrolyte loss through vomiting—a hypochloremic metabolic alkalosis (serum bicarbonate \( [HCO_3] \) levels ≥ 29 mmol/dL and chloride levels ≤ 98 mmol/dL), although these abnormalities may be absent early in the disease course.

Hypertrophic pyloric stenosis may be confirmed by ultrasonography or upper GI series. Ultrasonography is the diagnostic modality of choice because it is simple, readily available, without serious complications such as aspiration and, in skilled hands, may even be performed by the emergency clinician. With both modalities, reported accuracy is greater than 95%. On ultrasound, the pylorus appears thickened (pyloric muscle thickness > 4 mm; pyloric diameter > 14 mm) and elongated (>19 mm), which is diagnostic. A characteristic string sign, reflecting passage of contrast material through the narrowed pyloric sphincter, may also be evident. In advanced stages with complete obstruction at the pylorus; plain films may reveal a distended, air-filled stomach (Fig. 171.2).

Differential Considerations. Vomiting in infants is common, and the differential diagnosis is broad. Usually, infants present early in the disease progression and are well-appearing. In these infants, the common consideration is differentiating hypertrophic pyloric stenosis from gastroesophageal reflux. Reflux classically begins shortly after birth and remains relatively constant. Infant with pyloric stenosis typically have progressively worsening emesis beginning around 2 or 3 weeks of life. In advanced stages, it occurs with every feed and is often described as projectile.

Infants who present with sudden onset of severe vomiting and bilious emesis, or who are ill-appearing, should be evaluated for other surgical emergencies, including malrotation with midgut volvulus, duodenal atresia, and necrotizing enterocolitis. With reflux and pyloric stenosis, emesis is rarely bilious.

Many causes of vomiting do not have a true GI origin, including sepsis, metabolic disturbances (eg, diabetic ketoacidosis), increased intracranial pressure, middle ear disturbances, urinary tract infections, inborn errors of metabolism, pain, medications, and drug intoxications. Differential considerations for vomiting in children vary by age (Table 171.4).

Management

Treatment consists of fluid and electrolyte replacement and surgical consultation. Hypertrophic pyloric stenosis is not a true surgical emergency, but may be a fluid and electrolyte emergency. Fluid resuscitation should begin with repeated boluses of 20 mL/kg of normal saline as necessary to treat dehydration and hypovolemic shock. Potassium supplementation (KCl, 0.5 to 1 mEq/kg IV over 1 to 2 hours) is often necessary. Definitive management is surgery. The corrective procedure, called a pyloromyotomy, may be performed open, referred to as the Ramstedt pyloromyotomy, or laparoscopically. Associated mortality is rare.

Disposition

Most children are best managed with hospital admission for rehydration and correction of electrolyte abnormalities in conjunction with urgent imaging and surgical consultation.

Malrotation With Midgut Volvulus

Principles of Disease

Malrotation occurs in 1 in 500 live births and has a male predominance of at least 2:1. Among infants with malrotation, symptomatic volvulus occurs in the first month of life in approximately one-third, in the first year of life in approximately half, and before the age of 5 years in 75% of children. Cases of adult midgut volvulus have been reported. Bilious emesis is the hallmark presentation. Malrotation with volvulus carries a mortality rate of 3% to 15%.

During embryologic development, the GI tract rotates around the superior mesenteric artery. As it completes the rotation, the duodenum forms a C-loop and is fixed to the retroperitoneum in the left upper quadrant at the ligament of Treitz. The cecum becomes similarly fixed in the right lower quadrant. Thus, the duodenum and cecum normally come to lie widely separated and are firmly fixed in position by peritoneal attachments called Ladd’s bands. They are only loosely connected by a broad-based mesentery. In cases of malrotation, the duodenum and cecum do not rotate completely, remain closely positioned, and are suspended in the midgut region by the mesenteric vascular stalk. This unusually close proximity results in a short stalk of mesentery that easily twists on itself, resulting in obstruction of the distal duodenum and bowel ischemia and necrosis secondary to compression of the superior mesenteric artery.

Clinical Features

Infants classically present with sudden-onset bilious emesis and abdominal distention. Any pigmented staining of the vomitus suggests the presence of bile. When bile is initially produced, it is bright yellow and turns green only with time and oxidative exposure. Differential coloring of bile-stained emesis, yellow versus green, is not predictive of a surgical condition. Infants usually appear quite ill and may present in shock.

Diagnostic Considerations

Diagnostic Testing. The diagnostic procedure of choice to identify midgut volvulus is a limited upper GI contrast series, which reveals an abnormal position of the duodenal C-loop (Fig. 171.3) and small bowel, with a characteristic corkscrew appearance (Fig. 171.4). Other diagnostic strategies may include plain films of the abdomen and ultrasonography. Findings on plain abdominal films may include air-fluid levels suggesting obstruction, abnormally dilated bowel loops overlying the liver, and a paucity of small bowel gas distally (Fig. 171.5). Ultrasonography, usually performed to evaluate for hypertrophic pyloric stenosis, may reveal an abnormal orientation of the superior mesenteric artery and vein (the vein is abnormally positioned anteriorly or to the left of the artery; Fig. 171.6) or a whirlpool sign caused by the vessels twisting around the mesenteric stalk, causing an echogenic twisting pattern. The role of ultrasonography in the direct evaluation for midgut volvulus has yet to be determined. CT is usually not recommended as it carries the risk of additional radiation without benefit of improved diagnostic ability over upper GI series.

Differential Diagnoses. Vomiting in childhood is common and occurs across a wide spectrum of illnesses (see Table 171.3).

Causes vary by age, progression of symptoms, and vomitus appearance. Acute bowel obstruction usually causes sudden-onset vomiting, which is usually bilious. In a neonate, bilious vomiting may indicate malrotation with volvulus or other acute bowel obstructive process. Gastroesophageal reflux disease (GERD) and hypertrophic pyloric stenosis typically cause nonbilious emesis in relatively well-appearing infants. NEC may also present with obstructive signs and symptoms, including bilious emesis and abdominal distention but, unlike malrotation with volvulus, NEC is characterized radiographically by diffusely dilated loops of small bowel and the presence of air within the bowel walls, termed pneumatisosis intestinalis.14

### Management

Emergent pediatric surgical consultation should be obtained for any neonate or infant with bilious vomiting, even before diagnostic studies have been performed. In acute midgut volvulus, operative intervention must be rapid to save the bowel from necrosis.

Intravenous (IV) access should be obtained, and laboratory studies should include blood glucose level, a CBC with differential, electrolyte values, and renal and liver function tests. Repeated fluid boluses of 20 mL/kg of normal saline should be given until adequate circulation has been reestablished. Ill-appearing infants

---

**Fig. 171.4.** Upper gastrointestinal film, obtained in the same infant as in Fig. 171.3, reveals abnormal positioning of the duodenal C-loop to the right of the spinal column, consistent with malrotation. (Courtesy Dr. Mark A. Hostetler.)
should receive empirical, broad-spectrum antibiotic coverage. A nasogastric or orogastric tube should be placed. A limited upper GI series should also be emergently obtained, but should not delay resuscitation and surgical consultation.

Disposition

Patients with a confirmed or equivocal diagnosis should be admitted with emergent surgical consultation.

Necrotizing Enterocolitis

Principles of Disease

NEC, the most common GI emergency in neonates, affects up to 4000 US infants every year. NEC is also the most common cause of intestinal perforation during the newborn period. Because most affected infants are premature and acquire the condition in the NICU, NEC usually is not considered a disease of the ED. NEC does occur in a small subset of late preterm and full-term infants, although most of them have other underlying illnesses and rarely are discharged from the NICU prior to the onset of disease. Complications in children who survive NEC include strictures, fistulas, and short gut syndrome.

The exact pathophysiologic mechanism of NEC is unclear but is likely multifactorial. Prematurity is the most common and universally accepted risk factor; 90% of all affected infants are born prematurely. The primary pathologic event may be inflammation or injury to the intestinal wall, beginning in the mucosa and extending transmurally.

**Fig. 171.5.** Spot film from the upper gastrointestinal series obtained in the infant in Fig. 171.3. This radiograph shows the characteristic cork-screw appearance seen on small bowel follow-through in patients with malrotation. (Courtesy Dr. Mark A. Hostetler.)

**Fig. 171.6.** Ultrasonographic findings in malrotation with midgut volvulus. **A,** Abnormal orientation of mesenteric vessels associated with malrotation with midgut volvulus. Normally, the superior mesenteric vein (SMV) is positioned to the right of the superior mesenteric artery (SMA). In malrotation, the vein is abnormally positioned anteriorly or to the left of the artery. **B,** Whirlpool sign caused by the vessels twisting around the mesenteric stalk, resulting in an echogenic twisting pattern. AO, Aorta. (Courtesy Dr. Patrick J. Maloney.)
Clinical Features

Infants with NEC first usually develop feeding intolerance and bilious or nonbilious emesis. In the more advanced stages of the disease, infants may appear extremely ill, with hematemesis, hematochezia, fever, and shock. Abdominal radiographs commonly show intestinal dilation, pneumatosis intestinalis, and perforation.

Diagnostic Considerations

Differential Diagnoses. Feeding intolerance and vomiting are common and nonspecific findings in neonates. Infants with NEC are usually quite ill-appearing. GERD classically begins shortly after birth and remains relatively constant in character. Pyloric stenosis–related vomiting does not begin until 2 to 3 weeks of age and then becomes increasingly severe and projectile. In neonates, bilious vomiting requires careful consideration to rule out other obstructive pathology, including malrotation with midgut volvulus. The appearance of the plain radiographs may help differentiate NEC and volvulus. Volvulus is associated with a paucity of small bowel gas, whereas the hallmark of NEC is diffusely dilated loops of small bowel and pneumatosis intestinalis.

Diagnostic Testing. Plain abdominal radiographs are the imaging study of choice in NEC. Radiographs may show nonspecific dilated loops of bowel, intramural air (pneumatosis intestinalis), which is pathognomonic for NEC (Fig. 171.7), air within the portal system and biliary tract, or pneumoperitoneum. Pneumatosis is present in 75% of patients with NEC. No individual laboratory test is diagnostic or specific for NEC, but may reflect dehydration, electrolyte derangements, and sepsis.

![Fig. 171.7. Plain radiograph obtained in an infant with necrotizing enterocolitis. Straight arrows indicate air within the wall of the small bowel and gastric mucosa (pneumatosis intestinalis and gastralis). Curved arrows indicate air in the biliary tree (portal venous gas). (Courtesy Dr. Mark A. Hostetler.)](image)

Management

Patients suspicious of having NEC should receive nothing by mouth (NPO), with placement of an orogastric or nasogastric tube for decompression of the stomach and small bowel. Because these patients are frequently hemodynamically unstable and may have periods of apnea or significant respiratory distress, the airway should be managed as indicated. IV or intraosseous access should be established; laboratory studies should include a CBC with differential, electrolyte panel, renal and liver function tests, and type and screen. A bedside blood glucose level should be determined. Blood and urine cultures should be obtained. Fluid resuscitation with 20 mL/kg boluses of normal saline should be repeated until adequate circulatory volume has been achieved. Vasoactive agents such as dopamine, epinephrine, or norepinephrine are indicated for patients in refractory shock. Broad-spectrum antibiotic coverage is indicated (Box 171.2). Emergent pediatric surgery consultation should be obtained in all cases because perforation and bowel necrosis may not be immediately evident on plain radiographs.

Disposition

Children thought to have NEC require admission to an ICU and should have emergent pediatric surgical consultation.

Gastroesophageal Reflux

Principles of Disease

GERD, one of the most common causes of vomiting during infancy, refers to the regurgitation of stomach contents into the esophagus. GERD occurs as a result of an incompetent lower esophageal sphincter. Chronic reflux of gastric contents into the esophagus may result in esophagitis, aspiration, and failure to thrive if it is severe.

Clinical Features

GERD generally begins shortly after birth and resolves with time, usually by the age of 1 year. Clinical manifestations occur along a wide spectrum of disease, ranging from asymptomatic to occasional episodes of spitting up to severe persistent vomiting and

</table>
failure to thrive. Sandifer’s syndrome, although rare, refers to the stereotypical opisthotonic movements highly suggestive of severe GERD. GERD may occasionally be associated with brief periods of apnea and pallor, apparent life-threatening events, or respiratory symptoms, including chronic coughing, recurrent stridor, and persistent wheezing.

Diagnostic Considerations

Differential Diagnoses. Children with GERD exhibit nonbilious emesis that begins shortly after birth and is relatively constant over time. Unlike pyloric stenosis, vomiting is usually neither progressive nor projectile. Most children with GERD of milder severity continue to gain weight.

Diagnostic Testing. In the ED, the diagnosis of GERD is typically made on the basis of the history and physical examination. However, ill-appearing infants in whom the diagnosis is uncertain may benefit from diagnostic studies; these tests, such as esophageal pH probes, barium swallow studies, and direct visualization by endoscopy, should be conducted in consultation with a pediatric gastroenterologist.

Management

Most infants respond to conservative lifestyle modifications, such as smaller feedings, frequent burpings, formula thickened with cereal, and a semiupright position after feeding. Pharmacologic regimens are not recommended for infants with uncomplicated reflux (so-called happy spitters). Although lacking supportive evidence, acid suppression can be used, but should be reserved for those with more severe symptoms, such as esophagitis, weight loss, or significant irritability, in whom more conservative lifestyle modifications have failed. Severe and refractory cases occasionally require Nissen fundoplication.

Disposition

Most children may be discharged home safely with conservative measures. Children with more severe symptoms or poor weight gain should be referred to a pediatrician or pediatric gastroenterologist for testing and additional pharmacologic management. Those with severe dehydration, weight loss, or failure to thrive should be admitted.

Intussusception

Principles of Disease

Intussusception refers to the invagination of part of the intestine into itself. It is the most common cause of intestinal obstruction in children younger than 2 years, occurring most frequently in infants 5 to 12 months of age. In contrast to adults, most cases of intussusception in children are idiopathic, occurring in healthy children. The exact cause of intussusception is unclear, but the most prevalent theory relates to a lead point that causes telescoping of one segment of the intestine into another. Bowel wall edema develops, resulting in mechanical obstruction and vascular compromise. The end result is bowel wall ischemia and necrosis.

Intussusception may occur at any point along the GI tract. Ileocolic intussusceptions are most common. In younger children, lead points are usually the result of enlarged Peyer’s patches secondary to a recent viral infection. Approximately 75% of cases, especially in children older than 5 years, have a pathologic lead point; lesions include HSP vasculitis, Meckel’s diverticulum, lymphoma, polyps, postsurgical scars, celiac disease, and cystic fibrosis. Ileoileal intussusception occurs more frequently in children with HSP.

Clinical Features

The classic triad of clinical findings in intussusception consists of abdominal pain, a palpable sausage-shaped abdominal mass, and bloody stools, described as currant jelly. All three features are present in a minority of patients, however. Abdominal pain is the most common symptom. The child experiences cyclic episodes of severe abdominal pain as waves of peristalsis cause bowel dilation adjacent to and proximal to the involved bowel. These episodes typically last 10 to 15 minutes and occur in intervals of 15 to 30 minutes. During the painful episode, the child may be irritable and incontinent, often described as drawing the legs up to the abdomen and screaming in pain. Vomiting may be present. Blood, gross or occult, may be present in the stool. Diarrhea containing mucus and blood constitutes the classic currant jelly stool, a relatively infrequent and late finding. Occasionally, children present with atypical symptoms, including altered level of consciousness and profound lethargy, rather than the more typical abdominal pain syndrome.

Diagnostic Considerations

Differential Diagnoses. Differential considerations for abdominal pain in children by age are listed in Table 171.4. A slow progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. A sudden onset of severe pain is usually associated with acute obstruction or vascular occlusion, as seen with intussusception, volvulus, or torsion of the testicle or ovary. Children with intussusception classically have severe intermittent colicky pain. Children with ischemic pain exhibit symptoms out of proportion to the physical examination findings.

Diagnostic Testing. Initial screening radiographs of the abdomen may be obtained, but findings are usually nonspecific. Images should be examined for evidence of a soft tissue mass or mass effect, dilated loops of small bowel and a paucity of gas in a decompressed colon suggesting obstruction, a target sign (representing air in the intussusceptum as it telescopes into adjacent bowel), meniscus sign (representing air compressed like a meniscus from invaginating bowel), and free air (Fig. 171.8). Rarely, normal radiographs can likely exclude the diagnosis of intussusception, revealing complete visualization of the entire colon, with the presence of air throughout, including in the cecum. Indeterminate or nonspecific findings are common and do not exclude the diagnosis.

Ultrasoundography is the diagnostic imaging modality of choice. In skilled hands, it is highly sensitive and specific. The classic finding is a target sign (also referred to as a bull’s eye or doughnut sign), visualization of the telescoping intestinal wall in the transverse or cross-sectional view. When visualized in the longitudinal plane, it is referred to as the pseudo–kidney sign (Fig. 171.9). Contrast enemas have the advantage of being diagnostic and therapeutic. Occasionally, in children with the triad of paroxysms of pain, vomiting, and blood in the stool, contrast enemas may be safely done as first-line therapy (Fig. 171.10). Air-contrast enemas are equally efficacious. Either type of enema requires readily available backup by a pediatric surgeon in case of the bowel to reduce or iatrogenic perforation.

Management

IV fluids should be given in repeated boluses of 20 mL/kg of normal saline until adequate intravascular volume has been
Hirschsprung’s Disease

Principles of Disease

Hirschsprung’s disease accounts for approximately 20% of cases of partial intestinal obstruction in early infancy. Hirschsprung’s disease occurs at a rate of 1 in 5,000 live births and is four to five times more common in boys. Cases are usually sporadic in occurrence but may be associated with Down syndrome or other congenital anomalies.

Hirschsprung’s disease refers to congenital aganglionosis of the colon—that is, an absence of ganglion cells in the myenteric plexus of the distal colon. The anus is invariably involved, with aganglionic bowel usually extending proximally 4 to 25 cm. The absence of colonic ganglion cells interferes with that segment’s ability to relax, creating a functional obstruction. Stool
accumulates proximal to the level of obstruction and produces dilation of the colon (ie, megacolon).

Clinical Features

Neonates with Hirschsprung’s disease often present in the nursery with failure to pass meconium; however, a spectrum of disease is recognized, and presentation may be later in life. Infants brought to the ED usually have a history of chronic constipation. Vomiting, irritability, poor weight gain, failure to thrive, and abdominal distention may be present. Children who appear ill, with fever, should be evaluated for enterocolitis and toxic megacolon.26

Diagnostic Considerations

Differential Diagnoses. Constipation is one of the most common causes of abdominal pain and vomiting in children. Infants during the first few months of life may have normal stool frequencies that range from one per feeding to one every few days, with breast-fed infants having more frequent stools than formula-fed infants. Truly pathologic causes of constipation are uncommon. In addition to Hirschsprung’s disease, considerations include cystic fibrosis, infantile botulism, and hypothyroidism.

Diagnostic Testing. Plain films of the abdomen are usually nonspecific and may reveal evidence of fecal impaction with proximal obstruction, air-fluid levels, and a dilated colon. Barium enema studies revealing a narrowed aganglionic segment with proximal dilation is highly suggestive of Hirschsprung’s disease. The diagnosis is confirmed by biopsy or manometry.

Management

Initial management is focused on ensuring adequate fluid and electrolyte status. Abdominal films should be obtained. With evidence of acute obstruction, such as marked bowel dilation, decompression with a rectal tube may be necessary. Children who appear ill, with fever, should be evaluated for enterocolitis and toxic megacolon or bowel perforation. Definitive therapy of Hirschsprung’s disease is surgical, with resection of the aganglionic segments.26

Disposition

Unless a child appears ill, most constipated children may be managed safely on an outpatient basis.

Meckel’s Diverticulum

Principles of Disease

Meckel’s diverticula are remnants of the omphalomesenteric duct and contain bowel wall, with 60% containing heterotopic tissue, usually gastric mucosa. Bleeding occurs when acid secretion from the ectopic gastric mucosa causes ulceration and erosion. Meckel’s diverticulum is the most common congenital malformation of the small intestine.

Meckel’s diverticula traditionally follow so-called the rule of 2’s. The diverticulum is 2 cm wide, 2 cm long, and located within 2 feet of the ileocecal valve. Moreover, the condition occurs in 2% of the population, and only 2% of affected patients ever become symptomatic. Of symptomatic patients, 50% manifest symptoms by the age of 2 years, and most present by the age of 20 years.

Clinical Features

Patients classically present with massive, painless rectal bleeding. Some children may have complaints of abdominal cramping. The abdominal examination is usually benign. The blood is often described as brick red, but may range from melena to bright red. Complications may include intussusception, obstruction, perforation, and peritonitis.

Diagnostic Considerations

Differential Diagnoses. Massive GI bleeding is uncommon in childhood. Children commonly eat or drink substances containing red dyes that lead to changes in the stool’s color that may be mistaken for hematochezia. In addition, bismuth subsalicylate (eg, Pepto-Bismol), iron, and spinach may cause black stools falsely appearing melanotic. A simple Hemoccult test of stool or Gastrocult test of emesis can confirm the presence or absence of hemoglobin.

Similar to adults, the location of bleeding may be theorized on the basis of appearance of the blood. Hematemesis suggests bleeding proximal to the ligament of Treitz. Melena results from bleeding beyond the ligament of Treitz but proximal to the ileocecal valve. Hematochezia implies bleeding from the colon. Occasionally, in young children, GI transit time may be rapid enough to cause an upper GI source to cause hematochezia.

In neonates, the cause of GI bleeding is usually never identified. In young breast-fed neonates, an Apt test may be performed to differentiate fetal from swallowed maternal blood. Nursing mothers should be asked about cracked bleeding nipples. Milk protein allergy is another common cause of GI bleeding in infancy. Affected children are typically younger than 6 months, with a history of sudden-onset, mucoid, blood-streaked stools. Table 171.5 lists the differential considerations for GI bleeding in children by age.

Diagnostic Testing. A technetium-99m (99mTc) scan, also known as a Meckel’s scan, is the diagnostic modality of choice and has an accuracy of 90% when ectopic gastric mucosa is present; 99mTc has an affinity for gastric mucosa.27 A computed tomography (CT) scan of the abdomen may be performed to look for signs of inflammation or obstruction. Definitive diagnosis is confirmed by laparoscopy or laparotomy.

Management

Management of GI bleeding begins by assessment of circulatory status and volume resuscitation, as indicated. In cases of minimal or mild bleeding in otherwise healthy and well-appearing children, laboratory studies are unlikely to be useful. When there is concern for more serious disease, screening laboratory studies should include a CBC, coagulation studies (eg, prothrombin time, partial thromboplastin time), and typing and screening; a pediatric surgeon should be consulted.

Disposition

Children with massive GI bleeding suspicious for Meckel’s diverticulum should undergo a Meckel’s scan.27 Children with minor bleeding may be discharged home with close follow-up. Children with ongoing active bleeding should be hospitalized.

Henoch-Schönlein Purpura

Principles of Disease

HSP, also known as anaphylactoid purpura, is a hypersensitivity vasculitis with immune complex deposition with immunoglobulin A; it mainly affects the arterioles and capillaries. Although it is most well-known for its characteristic petechial to purpuric rash, HSP is a systemic vasculitis affecting any vessels.
HSP is commonly associated with abdominal pain, palpable purpuric rash, arthralgias, and renal disease. It is most common in children 4 to 11 years of age and occurs during the spring season following viral upper respiratory infections.

Clinical Features

Symptoms include abdominal pain, nausea, vomiting, and diarrhea. Patients are usually diagnosed clinically on the basis of the classic palpable purpura located on the buttocks and lower extremities (Fig. 171.11). Up to 70% of patients have GI complaints, including bleeding and ileoileal intussusception. Microscopic hematuria occurs in 50%. The syndrome is often relapsing and remitting for several weeks and may be associated with arthralgias. Neurologic involvement is less common in children.

Fig. 171.11. Henoch-Schönlein purpura in a 7-year-old child. Note the typical red-purple rash on the lower extremities. (Courtesy Dr. Marianne Gausche-Hill.)

Diagnostic Testing. Patients are usually diagnosed clinically on the basis of the classic rash. All children with clinically diagnosed HSP should have a urinalysis for evaluation of renal involvement—white cells, red cells, casts, and protein. Those with apparent renal involvement should have serum electrolyte and creatinine levels measured. Patients with an uncertain diagnosis should have a CBC with differential, coagulation studies, blood culture, and sedimentation rate. Patients with HSP do not have thrombocytopenia. Children diagnosed with HSP who have worrisome abdominal pain should be evaluated for intussusception.

Management

Most children with HSP require only supportive management. Mild and moderate pain is usually well-controlled with
nonsteroidal antinflammatory drugs (NSAIDs) or acetaminophen. Management of HSP with glucocorticoids is controversial. Glucocorticoids have been shown to reduce pain associated with HSP, but have not been shown to affect the other disease complications, including nephropathy.8,26 Prednisone, at a dose of 1 mg/kg/day (maximum, 60 mg), is reserved for patients with severe symptoms, including severe abdominal pain, GI bleeding, hematuria, or severe arthralgias, usually in consultation with a rheumatologist.

Disposition

Most patients can be managed symptomatically with close outpatient observation and follow-up. Indications for hospital admission include uncertain diagnosis to exclude the possibility of meningococcemia, severe abdominal pain, and intractable vomiting. Additionally, a set of six criteria, with the presence of at least one of these criteria, predicts the need for hospitalization—orchitis, moderate or severe abdominal pain, polyarthritis, GI bleeding, and inability to ambulate.27 Those with compromised renal function should have a nephrology consultation and also should be considered for admission, particularly if presenting with hypertension.

Inflammatory Bowel Disease

Principles of Disease

Approximately 20% of patients with IBD develop symptoms before the age of 20 years. Most patients do not experience symptoms until adolescence. IBD is rare in children younger than 1 year.31 Ulcerative colitis is an inflammatory disease primarily involving the mucosa and submucosa of the rectum and distal colon. Crohn’s disease is a transmural inflammatory disease that may involve any portion of the intestinal tract. Chronic inflammation may result in the formation of an abscess, fistula, or stricture. Crohn’s disease is commonly associated with extraintestinal manifestations, especially in children.

Clinical Features

Although patients experiencing complications frequently present to the ED, the diagnosis is rarely made in this setting. Usually, children with known disease present in the midst of an acute flare, usually with increased frequency of diarreal stools, bloody diarrhea, abdominal pain, and occasionally fevers. Patients with toxic megacolon or perforations are usually febrile and volume-depleted and demonstrate significant abdominal tenderness. There are also extraintestinal manifestations and include fever, anemia, oral ulcerations, erythema nodosum, pyoderma gangrenosum, uveitis, liver dysfunction, and failure to thrive.

Diagnostic Considerations

Diagnostic Testing. Acute IBD flares are usually diagnosed clinically. Patients who appear ill may require plain films to evaluate for toxic megacolon or bowel perforation. Screening laboratory studies should include a CBC with differential and platelet counts, typing and screening, and electrolyte panel. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels may also be beneficial in the diagnosis and management because most patients have elevated levels at the time of diagnosis, as well as with acute flares.

Differential Diagnoses. There are a large number of differential considerations for abdominal pain and GI bleeding (see Tables 171.4 and 171.5). Gastroenteritis is the most common consideration in this clinical scenario. Children experiencing their first episode of IBD and children outside the usual age at presentation are much more likely to be misdiagnosed with acute gastroenteritis.

Management

Management in the ED begins with attention to volume status and resuscitation with repeated boluses of 20 mL/kg of normal saline until the volume status is adequate. Acute exacerbations should be treated in conjunction with a gastroenterologist. Corticosteroids (eg, prednisone, 1 mg/kg/day; maximum dose, 60 mg/day) are usually recommended for mild to moderate exacerbations. Other agents commonly used include sulfasalazine and azathioprine, along with other immunosuppressive agents.32,33 Patients with suspected toxic megacolon require IV broad-spectrum antibiotic therapy and surgical consultation.

Disposition

Children not diagnosed with IBD but who have recurrent GI symptoms or a family history of IBD should be referred to a pediatric gastroenterologist for further evaluation. With acute flares, indications for admission include dehydration, toxic or ill appearance, and inability to tolerate oral fluids. Children with evidence of toxic megacolon should have a surgical consultation.

Gastrointestinal Foreign Bodies

Principles of Disease

GI foreign bodies usually are seen in children younger than 5 years and in those with developmental delays. Coins, small toys, magnets, batteries, and jewelry are the most common esophageal foreign bodies in children, compared to food boluses in adults. Most ingestions in children are accidental. Most swallowed foreign bodies pass through the entire GI tract without complications. However, foreign bodies commonly become lodged in one of three areas of normal physiologic narrowing—upper esophageal sphincter (cricopharyngeus muscle), thoracic inlet (C6-T1); aortic arch, tracheal bifurcation (T4-6); and lower esophageal sphincter, diaphragmatic hiatus (T10-11).34 Of objects that have made it into the stomach, 80% to 90% are passed without complications.

Clinical Features

Many accidental ingestions go unwatched. Children may gag as they attempt to swallow the object. Objects aspirated into the respiratory tract generally produce persistent coughing, wheezing, and increased work of breathing. Children who swallow objects into the GI tract may remain asymptomatic or develop a wide spectrum of symptoms, including food refusal, persistent gagging, drooling, continuous dry heaves, or wheezing.35 Larger foreign bodies may compress the airway and cause respiratory distress.

Complications are more likely to occur when foreign bodies have been impacted for an extended period of time. Progressive dysphagia, pain, respiratory distress, or fever is suspicious for esophageal or intestinal perforation.

Swallowed button batteries warrant special mention. Button batteries lodged in the esophagus cause severe mucosal erosions, severe burns, and mediastinitis in as little as 2 hours, most likely as a result of the electrical current discharged from lithium batteries. GI consultation for emergent foreign body removal is necessary. Button batteries in the stomach usually pass without complications and do not require removal unless they fail to pass.
the pylorus within 48 hours of ingestion. The National Capital Poison Center operates a 24/7 website (www.poison.org/battery) and hotline (202-625-3333) for battery ingestion cases.

On occasion, objects pass into the stomach that are too large to pass through the pylorus. As a general rule, objects longer than 5 cm and wider than 2 cm are less likely to pass the pylorus spontaneously. Persistent vomiting may herald obstruction. If not removed, foreign bodies may, over time, result in erosion, perforation, infection, stricture, or fistula formation.

**Diagnostic Considerations**

**Diagnostic Testing.** Plain radiography is the most common method of diagnosing and locating foreign bodies. Classically, coins in the esophagus project en face (round) in the frontal (coronal) view (Fig. 171.12). When coins are lodged in the upper airway, they will project on end in the frontal view. Occasionally, it may be difficult to differentiate the appearance of a coin from a button battery radiographically. A button battery will typically have a distinctive double-rim contour on radiographs (Fig. 171.13).

**Differential Diagnoses.** Not all foreign bodies are radiopaque and visible with standard radiography. Patients who remain symptomatic require further contrast-enhanced imaging or direct visualization.

**Management**

Most GI foreign bodies will spontaneously pass without complications. In general, if the object has made it into the stomach, further treatment or routine serial imaging is unnecessary. Patients with button batteries located in the stomach represent an exception in that they require repeated films to ensure passage.

**Fig. 171.12.** Plain radiographs obtained in a child with an esophageal coin foreign body. Posteroanterior (A) and lateral (B) views show the expected orientation for a coin lodged in the esophagus. (Courtesy Dr. Mark A. Hostetler.)

**Fig. 171.13.** Esophageal button battery. It may be difficult to differentiate the appearance of a coin from a button battery radiographically. However, a button battery will typically have a distinctive double-rim contour on radiographs, as seen in this posteroanterior radiograph. (From: Lin VYW, Daniel SJ, Papsin BC: Button batteries in the ear, nose and upper aerodigestive tract. Int J Pediatr Otorhinolaryngol 68:473–479, 2004.)
Appendicitis

Principles of Disease

Appendicitis is the most common surgical condition involving the abdomen and the most common nontraumatic surgical emergency in children. Appendicitis develops in approximately 1 of every 15 people sometime during their lifetime. The peak age of incidence is between 9 and 12 years, and it is uncommon in children younger than 5 years.

The appendix is a blind pouch that may become obstructed, resulting in edema, vasocongestion, inflammation, ischemia, infarction, necrosis, and perforation. In adults, a thicker appendiceal wall resists perforation, and a well-developed omentum aids in walling off the infection to prevent its diffuse spread. Children have neither, so rupture tends to occur earlier, and diffuse peritonitis develops more readily.

Morbidity and mortality related to acute appendicitis increase significantly if the appendix ruptures prior to operative management. Therefore, the goal of management is diagnosis and operative management prior to appendiceal perforation. Perforation seems to be directly related to the duration of symptoms. In children, the rate of appendiceal perforation varies inversely with age. Perforation is highest among children younger than 5 years, among whom more than 50% are ruptured at the time of surgery. This likely reflects, at least in part, the fact that preschool children have a limited ability to describe their symptoms.

Clinical Features

Patients classically present with a constellation of symptoms that includes abdominal pain, nausea, vomiting, and anorexia. Symptoms are gradually progressive over the first 24 hours. Abdominal pain is usually first described as vague, crampy, and periumbilical. Pain becomes more severe, constant, and localized to the right lower quadrant as the disease progresses. Fever usually develops later or not at all. Patients may have a multiphasic course to their illness, with symptom resolution followed several days later by the development of fever, chills, and abdominal pain. This likely represents spontaneous appendiceal rupture and formation of an abscess.

The physical examination may reveal several typical findings. In patients with inflammation surrounding the appendix, peritoneal findings that localize to the right lower quadrant are typical. Pain occurs with movement; patients may be unwilling to jump up and down, and tapping their heels may cause abdominal pain. Bowel sounds are usually decreased or absent. Rebound tenderness may be elicited in the right lower quadrant. The Rovsing, psoas, and obturator signs are difficult to assess in young children and should not be relied on due to their poor sensities and specificities. The absence of the classic signs and symptoms of appendicitis does not exclude the diagnosis, especially in younger children.

Diagnostic Considerations

Diagnostic Testing. Appendicitis may be diagnosed clinically on the basis of the history and physical findings alone in children with a classic constellation of findings. Patients with an equivocal presentation should undergo a diagnostic evaluation. There are no sufficiently sensitive or specific laboratory tests that alone can confirm or exclude the diagnosis of acute appendicitis. Screening studies may include a CBC with differential, CRP, urinalysis, electrolyte levels, and renal and liver function testing. Pregnancy testing, vaginal wet mount, and gonorrheal and chlamydial testing should be considered in postpubertal females. Most children with acute appendicitis have an elevated white blood cell count (>10,000 × 10⁶/L) or absolute neutrophil count. Because it is neither sensitive nor specific enough, an elevated white blood cell count should not be exclusively used to diagnose or exclude appendicitis. An elevated CRP level (>0.6 mg/dL) has been shown to correlate with acute appendicitis, especially when symptoms have been present for longer than 24 to 48 hours. Acute appendicitis occasionally causes a mild sterile pyuria (<5 to 10 white blood cells/high-power field and an absence of bacteria) related to local inflammation of the right ureter.

Several clinical scoring systems have been developed to assist in the evaluation of appendicitis. The most widely studied prospectively include the Alvarado score, Pediatric Appendicitis Score, and Refined Low-Risk Appendicitis Rule. Each system relies on a combination of clinical factors and laboratory values to risk-stratify children into low-, moderate-, and high risk categories for acute appendicitis. Unfortunately, none of these have been shown to be sensitive and specific enough to be recommended alone for widespread clinical use.

Diagnostic imaging options include plain films of the abdomen, ultrasonography, and CT. Plain films have limited value in appendicitis and are not recommended in the routine evaluation of
appendicitis. Occasionally, an appendiceal fecalith will be evident (Fig. 171.14). Although the presence of an appendicolith in a child with acute abdominal pain is essentially pathognomonic for acute appendicitis, it is present in only 10% of cases.

Ultrasonography is routinely recommended as the first-line imaging modality in suspected appendicitis. It has the advantages of a lack of ionizing radiation and the ability to evaluate ovarian anatomy. Ultrasonographic findings consistent with appendicitis include an enlarged, noncompressible appendix (wall thickness > 2 mm; total appendix diameter > 6 mm) that is painful during scanning (Fig. 171.15A, B). Appendiceal ultrasound studies have reported sensitivities and specificities of more than 90% when the appendix is successfully visualized. Unfortunately, the ability to visualize the appendix adequately with ultrasound is limited in obese children and is highly user-dependent.

In the child in whom the appendix is not visualized or findings are equivocal with ultrasonography, clinical observation with serial examinations or CT imaging may be undertaken. CT in general has high sensitivity and specificity for unruptured and ruptured appendicitis, and the use of IV contrast seems to improve sensitivity slightly. Limited appendiceal CT protocols decrease the ionizing radiation exposure without sacrificing sensitivity or specificity. The increased use of CT has been shown to reduce the negative laparotomy rate without increasing the risk of perforation.

Differential Diagnoses. Differential considerations for abdominal pain by age are listed in Table 171.4. Mesenteric adenitis is the most common imitation of appendicitis. Similar to appendicitis, it often is associated with significant diffuse tenderness that may localize in the right lower quadrant. Children with mesenteric adenitis lack true peritoneal signs, however. Mesenteric adenitis usually follows a viral illness and results from nonspecific inflammation of the mesenteric lymph nodes.

Girls of reproductive age merit consideration of gynecologic pathology, including ectopic pregnancy, ovarian torsion, ovarian

![Fig. 171.14. Fecalith in a child with appendicitis. (Courtesy Dr. Marianne Gausche-Hill.)](image)

![Fig. 171.15. Ultrasound images obtained in children with appendicitis. Findings include an enlarged, noncompressible, tubelike structure in the longitudinal view with an appendicolith (A), an enlarged noncompressible structure seen in cross section (B) and, in another patient, an enlarged, poorly compressible structure with a moderate amount of free fluid consistent with acute perforation (C). (Courtesy Dr. Mark A. Hosteller.)](image)
Narcotics are safe and effective and should not alter the diagnostic administration of opioid pain medications and antiemetics. It is not necessary to continue antibiotics postoperatively. It is not necessary to continue antibiotics postoperatively. It is necessary to continue antibiotics postoperatively in those with a nonperforated appendicitis. Patients with a suspected perforation, signs or symptoms of sepsis, or unusual delay in surgical management should receive IV antibiotics in the ED and continued postoperatively.48,49

Disposition

Children with appendicitis should be hospitalized for appendectomy. Patients with nonspecific signs and symptoms in whom imaging studies are nondiagnostic should be observed for a period of 12 to 24 hours with serial exam examinations or, with adequate family and social support, discharged home, with careful instructions to return for reexamination.

Pancreatitis

Principles of Disease

Pancreatitis is uncommon in childhood, especially in children younger than 10 years. In adults, pancreatitis is usually caused by alcohol abuse and biliary tract disease. In children, pancreatitis is usually associated with trauma, infection, structural anomalies, systemic disease, and drugs or toxins. Idiopathic causes account for 30% of cases. Biliary obstruction should be considered in the adolescent.

The common pathophysiologic pathway of acute pancreatitis is inflammation, edema, and autodigestion of pancreatic tissue by pancreatic enzymes. In severe cases, the inflammatory cascade may progress to necrotizing or hemorrhagic pancreatitis. Other complications include the formation of abscesses, pseudocysts, and fistulas.

Clinical Features

Abdominal pain in the hallmark of pancreatitis in adults and children. Patients typically present with complaints of severe, constant epigastric pain that worsens gradually and radiates to the back. Nausea, vomiting, diarrhea, fevers, irritability, and lethargy are also described. Patients have significant abdominal tenderness in the epigastric area.

Diagnostic Considerations

Diagnostic Testing. Screening laboratory studies reveal elevations in the serum lipase level. The degree of elevation or serial changes are not always directly related to disease severity. Evidence of liver inflammation (elevated aspartate transaminase and alanine transaminase levels) and elevated bilirubin and alkaline phosphatase levels may be seen in patients with biliary obstruction. Plain films of the abdomen commonly show an ileus pattern, often with a sentinel loop of dilated small bowel in the left upper quadrant. An ultrasound study or CT may be helpful to evaluate anatomy for congenital malformations, biliary tract disease, pseudocyst, or abscess formation. In patients with respiratory distress, a chest radiograph may identify a secondary pleural effusion.

Differential Diagnoses. Slow progressive onset of pain is more likely to be associated with appendicitis, constipation, and pancreatitis. Sudden onset of severe pain is usually associated with acute obstruction or vascular occlusion, as seen with intussusception, volvulus, or torsion. Differential considerations for abdominal pain in children by age are listed in Table 171.4.

Management

Patients should receive volume replacement and electrolyte correction and maintained on an NPO status. IV fluids are given in repeated boluses of 20 mL/kg of normal saline until adequate vascular volume has been established. Patients should receive adequate symptomatic relief with parenteral narcotics and antiemetics. Steroids and antibiotics are not indicated.

Disposition

Children with acute pancreatitis require hospitalization. Children with known or recurrent disease, are able to self-hydrate, and have adequate analgesia may be managed as outpatients.

Biliary Tract Disease

Principles of Disease

Biliary tract disease is uncommon in childhood and has causes differ from those in older individuals. Cholestasis in the neonatal period is usually associated with biliary atresia, biliary cysts, infections, and other metabolic and genetic disorders. Gallstones in children are usually associated with hemolytic disease (eg, sickle

</table>
The diagnosis. Elevated white blood cell counts are nonspecific. Biliary tract disease is usually associated with elevations in alkaline phosphatase, liver enzyme, and inflammatory markers. Nausea, and vomiting. Jaundice occurs in one-third of patients. Postprandial right upper quadrant pain associated with fever, leukocytosis, and upper abdominal tenderness is characteristic of biliary obstruction. Admittedly rare, acute acalculous cholecystitis is a distinct entity in which acute inflammation of the gallbladder develops in the absence of stones.

Similar to adult patients, pediatric patients usually present with intermittent abdominal pain, a palpable sausage-shaped abdominal mass, and clay-colored stools; however, the triad occurs in less than one-third of patients. Children with intussusception may present atypically, with an altered level of consciousness (eg, lethargy) rather than abdominal pain. Bilious vomiting in the neonate should initiate a diagnostic evaluation for possible malrotation with volvulus or other intestinal obstructive pathology. Toxic-appearing infants with bilious emesis should receive antibiotics for suspected sepsis and a detailed evaluation.

Diagnostic Considerations

Diagnostic Testing. Biliary tract disease is usually associated with elevations in alkaline phosphatase, liver enzyme, and bilirubin levels; however, absence of elevations does not exclude the diagnosis. Elevated white blood cell counts are nonspecific. Although only 15% of gallstones in adults are calcified and visible on plain radiographs, 50% of stones in children are radiopaque. Ultrasonography is the imaging modality of choice. It cannot only determine the presence of gallstones, dilation of the gallbladder and common bile duct, gallbladder wall thickness, and pericystic fluid, but can reproduce pain on compression of the gallbladder (sonographic Murphy’s sign). When ultrasound findings are equivocal or normal, and clinical suspicion is high, cholecintigraphy biliary tract imaging (HIDA [hepatobiliary iminodiacetic acid] scan) can further assess the functional status of the gallbladder. Although its role in children is unclear, magnetic resonance cholangiopancreatography can assess the intrahepatic and extrahepatic ducts.

Differential Diagnoses. Pediatric biliary tract disease is uncommon in children and requires consideration of an underlying or coexistent disease. Differential considerations are listed in Table 171.4.

Management

Asymptomatic patients with incidental findings of gallstones require no further therapy in the ED and may be referred to a surgeon for outpatient care. Febrile patients require hospital admission, fluid resuscitation, IV antibiotics, and surgical consultation. Laparoscopic cholecystectomy is considered safe and effective in children.

Disposition

Indications for hospital admission for biliary disease include pain control, need for IV hydration, fever, and need for operative management.
CHAPTER 171: Gastrointestinal Disorders

171.1. What is the most common cause of jaundice in the newborn?
A. Breast milk jaundice
B. Crigler-Najjar syndrome
C. Gilbert's syndrome
D. Physiologic jaundice of the newborn
E. Toxoplasmosis, other (congenital syphilis and viruses), rubella, cytomegalovirus, and herpes simplex virus (TORCH) infection

Answer: D. Although each of these may be a cause of hyperbilirubinemia in the newborn, the most common cause of jaundice is physiologic jaundice of the newborn.

171.2. A 4-week-old white infant presents with projectile vomiting. The mother denies that the patient has a history of fevers, irritability, or signs suggestive of abdominal pain. On physical examination, you palpate an olive in the abdomen. Of fevers, irritability, or signs suggestive of abdominal pain. The patient is found to have an abdominal mass. What is the most likely diagnosis?
A. Appendicitis
B. Intussusception
C. Meckel's diverticulum
D. Diverticulitis
E. Hepatitis

Answer: B. The most likely diagnosis is intussusception, which is a common cause of abdominal mass in infants and can present with similar symptoms to appendicitis. Intussusception occurs when one part of the intestine invaginates into another part, causing a bowel obstruction.

REFERENCES:
171.3. An 11-month-old infant presents with vomiting. The patient’s mother reports that he has been crying out in pain intermittently throughout the day, at which times he brings his knees to his abdomen. In between these episodes, the patient acts normally and plays. He has not had a fever, but the mother complains that his stool earlier looked like currant jelly. On examination, you find a playful afebrile patient, with a soft nontender abdomen. Which of the following may be used as an initial screening examination?
A. Air contrast enema  
B. Barium enema  
C. Computed tomography scan of the abdomen-pelvis  
D. Ultrasound  
A. Upper endoscopy  

Answer: D. The initial screening examination for intussusception is abdominal ultrasonography. Although each of the other imaging modalities may be useful to exclude other diagnoses or identify intussusception, ultrasonography has high sensitivity and specificity and is the screening modality of choice.
Infectious Diarrheal Disease and Dehydration

Patricia Padlipsky | Taylor McCormick

PERSPECTIVE

Diarrheal disease is responsible for approximately three quarter million deaths worldwide, 72% of which occur in children younger than 2 years old. Diarrheal diseases account for one in nine pediatric deaths worldwide and is the second leading cause of death in children younger than 5 years old. The rotavirus vaccine has markedly reduced pediatric diarrhea-associated emergency department (ED) visits and hospitalizations. Acute diarrhea is defined as the abrupt onset of abnormally high fluid content in the stool with increased volume or frequency. As supported by the World Health Organization (WHO), “acute” diarrhea has a sudden onset and lasts no longer than 14 days; “chronic” or “persistent” diarrhea lasts longer than 14 days. This classification is important for epidemiologic studies and to identify the most likely offending organism. Protracted diarrhea has different causes, poses unique problems in management, and has a prognosis different from that of acute diarrhea. Acute infectious diarrhea can occur with or without vomiting. When it occurs with vomiting, it is often referred to as acute gastroenteritis (AGE).

Principles of Disease

Up to 9 L of exogenous fluid and endogenous secretions enter the adult proximal bowel each day, and proportionally even more in children. Ninety percent of fluid is absorbed in the small bowel and the remainder in the large bowel. Water follows osmotic gradients created by active and passive transport of electrolytes, sugars, and amino acids into the bloodstream by the following mechanisms:

- Sodium chloride absorption in the small bowel, with an exchange of cations (Na+/H+) and anions (Cl-/HCO3-)
- Electrogenic sodium absorption in the colon but also in the small intestine, wherein Na+ enters the cell through an electrochemical gradient; this mechanism is often damaged in acute diarrhea
- Sodium co-transport mechanism in the small bowel

Na+ absorption is coupled with the absorption of glucose, amino acids, and peptides. This mechanism often remains intact during acute diarrhea, making oral rehydration possible.

Pathophysiology

Infectious agents cause diarrhea by adherence, mucosal invasion, enterotoxin production, and cytotoxin production. Under normal circumstances, the absorptive processes for water and electrolytes predominate over secretion, resulting in net water absorption. Diarrhea occurs when this balance is disrupted, either as a result of increased secretion from the gastrointestinal tract, decreased absorption of fluids, or from inflammation.

Secretory diarrhea is the result of increased intestinal secretion of water into the gut lumen or an inhibition of absorption. For example, Vibrio cholera produces an enterotoxin, resulting in increased chile and bicarbonate secretion. Secretory diarrhea is characterized by the absence of expected reduction in stool volume with fasting, a stool pH above 6, and the absence of reducing substances in the stool. Other bacteria that produce enterotoxins include Salmonella, Shigella, Escherichia coli, and Clostridium difficile.

Osmotic diarrhea is caused by the presence of poorly absorbed solutes from altered bacterial gut flora, damage to the mucosal absorptive surface, or ingestion of substances. These substances create an osmotic gradient across the bowel lumen, resulting in intraluminal movement of water and electrolytes. Typical acute viral gastroenteritis produces injury to the small bowel epithelium with consequent disruption of microvilli, decreasing the absorptive area, and preventing normal fluid, electrolyte, and nutrient absorption. The illness is compounded if the colon is unable to compensate for the large fluid volume. Osmotic diarrhea is often characterized by diarrhea that decreases or stops with fasting, a stool pH below 6, and the presence of reducing substances in the stool.

Inflammatory processes can cause destruction of villous cells or dysfunction of cellular transporters, leading to loss of fluids and electrolytes, as well as mucus, proteins, and blood in the intestinal lumen. Dysentery, diarrhea associated with blood and mucus in the stool, implies a compromised bowel wall. Acute inflammation, caused by enteroinvasive organisms such as Salmonella, Shigella, and Campylobacter, leads to infiltration of the gastrointestinal tract by neutrophils, which release a host of enzymes and factors causing both increased secretion and decreased absorption by the intestinal tract. Although blood loss may be clinically appreciable, it is usually less significant than fluid and electrolyte losses. Infectious diarrhea can present with significant signs of dehydration and electrolyte abnormalities.

The pediatric patient has several physiologic factors that predispose them to more severe complications from vomiting and diarrhea. As a result of their relatively larger extracellular fluid compartments, children can lose proportionately more fluids through the gastrointestinal tract. Furthermore, the turnover of fluids and solute in infants and young children can be three times that of adults. This rapid turnover of fluids is the result of higher metabolic rates, increased body surface area to mass index, and higher body water content. Children also have limited stores of metabolic substrates such as fat and glycogen, limited ability or desire to access fluids when ill, and a more limited ability to conserve water through their kidneys compared to adults. These factors make children more susceptible to large fluctuations in fluid, electrolytes, and nutrients, resulting in hypoglycemia, electrolyte abnormalities, dehydration, and shock.
Some groups are at higher risk for developing serious complications of infectious diarrhea (eg, invasive disease, bacteremia, and sepsis). These include premature infants, very low birth weight infants (up to a year), young infants (younger than 3 months old), immunosuppressed or malnourished children, and those with chronic underlying conditions. Recent hospitalization, treatment with broad-spectrum antibiotics, and travel to developing countries are additional risk factors. Risks factors for death from diarrhea include age younger than 1 year; birth weight less than 2500 g; malnourishment; African American, Hispanic American, or American Indian ethnicity; immunocompromise; and illness during winter months.

**Clinical Features**

Infectious diarrhea can present with diarrhea alone or accompanied by vomiting (ie, AGE). Signs and symptoms usually begin 12 to 72 hours after contracting the infectious agent. If due to a viral infection, they may include vomiting (ie, AGE). Signs and symptoms usually begin 12 to 72 hours after contracting the infectious agent. If due to a viral agent, the condition usually resolves within 1 week. See Box 172.1 for a list of common signs and symptoms. The history and physical examination should help differentiate acute infectious diarrhea from other causes of vomiting and diarrhea (see Tables 172.8 and 172.9) and help estimate the degree of dehydration. History and physical examination can sometimes aid in determining the type of pathogen responsible, although this will rarely affect management. Box 172.2 summarizes important information to gather from the history.

Vital signs should be assessed relative to age norms. The evaluation of the child should begin with looking at the child from across the room in a position of comfort, noting the patient’s overall appearance, responsiveness, activity, and work of breathing (see Chapter 160). A head-to-toe physical examination of the patient should focus on signs of dehydration that may indicate another cause for the diarrhea (eg, otitis media, pylonephritis, appendicitis, diabetic ketoacidosis), or signs that indicate the disease may have become extra-intestinal or systemic—bone pain (osteomyelitis), altered mental status (meningitis), petechiae (hemolytic-uremic syndrome [HUS]).

Acute infectious diarrhea in developed countries is often self-limited. The clinical presentation, course of illness, and treatments depends on the etiology of the diarrhea and the host. In the United States, viruses are responsible for most cases of acute infectious diarrhea, with bacteria causing only 7% to 10% of cases in children. Parasites are uncommon in the immunocompetent patient unless they have traveled to endemic areas. Table 172.1 lists the most common viruses, bacteria, and protozoa that can cause acute infectious diarrhea in children in the United States. 

### Specific Etiologies

**Viruses**

In the United States and Europe, the majority of cases of diarrhea are caused by viral pathogens, with incidence peaking in the winter. The most common of these are rotavirus and norovirus. See Table 172.2 for presentation and associated characteristics.

*Rotavirus* is the leading cause of diarrhea worldwide among children younger than 5 years old.

**Symptoms** occur in 2% to 3% of children with rotavirus infection. The chronically ill or malnourished child often fails to repair damaged intestinal epithelium post rotavirus infection, leading to a vicious cycle of malnutrition and progressive epithelial injury.

Prior to the release of the 2006 and 2008 vaccines, rotavirus was responsible for over 600,000 office and ED visits and up to 77,000 hospitalizations each year. An effective vaccine against rotavirus exists and is recommended for all children 6 weeks to 24 months of age. The vaccine is given in two doses at 2 to 6 months and 5 to 16 months of age.

**Norovirus** is an enteric virus that can cause outbreaks in healthcare facilities. Norovirus is easily transmitted and can cause outbreaks in schools, colleges, or other institutions. The illness is contagious and can be transmitted through contact with infected individuals, or by ingesting contaminated food or water.

**Sapovirus** is another type of virus that can cause similar symptoms to norovirus, but is less common.

**Salmonella species** and **Shigella species** are bacteria that can cause bloody diarrhea, fever, and abdominal pain. These infections are common in children and can be transmitted through contaminated food or water.

**Cryptosporidium** and **Giardia intestinalis** are protozoa that can cause diarrhea and can be spread through contaminated water or food.

**Entamoeba histolytica** is a parasite that can cause amoebic dysentery, which is characterized by severe diarrhea, blood in the stool, and abdominal pain.

**ETEC, Enterotoxigenic E. coli.**

**BOX 172.2**

**Patient History**

- Behavior: Weight loss, amount and frequency of feeding, level of thirst, level of alertness, level of activity, lethargy, irritability, quality of crying, presence or absence of tears with crying, frequency of wet diapers in infants or urination in children
- Orthostatic symptoms
- Diarrhea: Duration, frequency, and amount of stools; consistency and content of stool; watery, blood, mucus
- Vomiting: Duration, amount and quality of the vomitus, time since last vomited
- Abdominal pain: Location, quality, radiation, severity per parent and child
- Signs of infection: Fever, chills, myalgia, rash, rhinorrhea, sore throat, cough
- Symptoms in relationship to eating and drinking
- Similar symptoms in other household members or school
- Similar episodes in the past
- Food history
- Water exposure and recent camping
- Travel to endemic or epidemic areas
- Household pets
- Past medical history; chronic medical problems, recent hospitalizations; vaccine status
- Current/recent antibiotic

rotavirus was available for a short time (1998 to 1999) until it was noted to be associated with increased risk of intussusception. This vaccine was subsequently withdrawn from the United States market. Two live rotavirus oral vaccines, RotaTeq (RV5) (Merck & Co., Inc.) licensed in 2006 and Rotarix (RV1) (GlaxoSmithKline Biologicals) licensed in 2008 are now approved for prevention of rotavirus gastroenteritis.25 Millions of infants in the United States have received the rotavirus vaccine since 2006. Each year, the vaccine prevents up to 50,000 hospitalizations of infants and young children in the United States. Rotavirus illness has also decreased among older children and adults that are not vaccinated, likely a result of community (“herd”) immunity.

The current rotavirus vaccines were not associated with intussusception in large pre-licensure trials. However, a post-licensure study done by Vaccine Safety Datalink found a slight increase in rates of intussusception in children vaccinated with the RV1 vaccine but not with the RV5 vaccine.15,14 The U.S. Food and Drug Administration (FDA) found up to 1.5 excess cases of intussusception per 100,000 vaccinated infants in the United States within 21 days following first dose of RotaTeq.15 Other international studies have also found a slight increase in the risk of intussusception.16 Although there may be a slight increased risk of intussusception following the oral vaccines, the Centers for Disease Control and Prevention (CDC) still recommends the rotavirus vaccine due to its benefits far outweighing the risks.

Human Caliciviruses (Norovirus and Sapovirus). Norovirus accounts for approximately 12% of severe gastroenteritis among children younger than 5 years old. As the number of rotavirus cases decreases, norovirus is becoming the most common cause of infectious diarrhea in children.17 In the United States, norovirus accounts for more than 90% of community outbreaks (cruise ships, schools, and hospitals) and responsible for more than 250,000 ED and clinic visits and 23,000 hospitalizations for children younger than 5 years old.18,21 Norovirus AGE is associated with more frequent and prolonged vomiting, but less fever, than AGE caused by rotavirus.22 Seizures are the most common central nervous system (CNS) complication, whereas encephalopathy is possible but rare.23 Clinical manifestations for Sapovirus are similar to those of norovirus.24

Astrovirus accounts for approximately 5% to 9% of cases of infectious diarrhea in children. In healthy children, it is an illness of short duration, although asymptomatic shedding continues up to several weeks after symptom resolution.25 Adenovirus is well known for causing infections of the respiratory tract along with pharyngitis, otitis media, and pharyngoconjunctival fever. Enteric adenovirus serotypes cause gastroenteritis, accounting for 2% to 4% of cases of acute infectious diarrhea in children. Asymptomatic shedding of the virus for months is common.26

The mainstay for treatment of viral enteritis is supportive care with rehydration and electrolyte correction.

Bacteria

The common bacterial organisms causing acute diarrhea in American children along with their presentations and associated characteristics are listed in Table 172.3, and their treatment is listed in Table 172.4.

Nontyphoidal Salmonella accounts for more than 98% of the cases of Salmonella in the United States. Infection can result in an asymptomatic carrier state, AGE, bacteremia, invasive disease, or a disseminated abscess syndrome. Salmonellae invade the mucosa of the distal small intestine and the colon; they produce a cholera-like enterotoxin and a cytotoxin, which can cause significant diarrhea and fluid and electrolyte abnormalities similar to patients with documented cholera. Sustained or intermittent bacteremia can occur and should be suspected in any patient with prolonged fever (fever in nontyphoidal Salmonella usually lasts about 48 hours). Patients with Salmonella bacteremia are at increased risk for developing extraintestinal infections. (These are seen in up to 10% of patients with Salmonella bacteremia.) Extraintestinal sites of infection can result in endocarditis, vascular infections, cholecystitis, hepatic and splenic abscesses, urinary tract infections, pneumonia, meningitis, septic arthritis, and osteomyelitis.28

Although it is uncommon, Salmonella serotype typhi is only found in humans and can cause a bacteremic illness often referred to as enteric or typhoid fever. Although uncommon in the United States, S. typhi is endemic in many other countries. Typhoid fever may be acquired during international travel and appear as a nonspecific febrile illness in young children in whom sustained or intermittent bacteremia may occur. Constipation can be the presenting symptom and is often seen early in the course of the disease, but diarrhea can also occur.29

Treatment of nontyphoidal Salmonella infection is usually supportive. However, for children with S. typhi infection, antibiotics are recommended. Relapse of enteric fever occurs in up to 15% of patients and requires retreatment. Treatment failures have occurred in people treated with cephalosporins, aminoglycosides, and furazolidone despite in vitro testing indicating susceptibility.30

Among Shigella isolates reported in industrialized nations, including the United States, most isolates found were Shigella sonnei (86%). Shigella flexneri, Shigella boydii, and Shigella dysenteriae, in descending order, make up the remainder of isolates.31 S. sonnei is the most common cause of dysentery in the United States. Extraintestinal symptoms and signs are relatively common in children with Shigella infection and may include hallucinations, confusion, and seizures. Reactive arthritis (Reiter’s syndrome) can occur weeks after the infection. Rare complications of Shigella infection include bacteremia, HUS, toxic megacolon, pseudo-membranous colitis, and encephalopathy (Ekiri syndrome). The risk of septicaemia increases in neonates, malnourished children, and infection with S. dysenteriae. There is some evidence that treatment is effective in shortening duration of diarrhea and hastening eradication of organisms from feces.32 Drug-resistant Shigella has been increasing since 2006. According to CDC surveillance data from 2011, resistance to traditional first-line drugs, ampicillin and trimethoprim-sulfamethoxazole, has become so high that physicians must rely on alternative drugs like ciprofloxacin and azithromycin.22,33 The CDC is starting to see the emergence of resistance to ciprofloxacin and azithromycin (1.6% and 3%, respectively).22

Campylobacter species cause a significant proportion of diarrheal disease worldwide, with 2.4 million cases yearly in the United States. According to data from the CDC, there has been a 30% decline in the incidence of infection since 1996.34 Of the five types, C. jejuni and C. coli are the most common.29 In neonates and young infants, bloody diarrhea without fever can be the only manifestation of infection. Febrile seizures can occur in young children before any gastrointestinal symptoms are present. The clinical presentation may be similar to acute appendicitis or intussusception. Severe or prolonged disease can mimic inflammatory bowel disease. Bacteremia is uncommon but can occur in children, including neonates. Immunocompromised hosts can have prolonged, relapsing, or extraintestinal infections. Antibiotic treatment is recommended, but most children will recover without treatment.30 Yersinia enterocolitica is a relatively uncommon cause of simple self-limited diarrhea and vomiting in the United States. According to the CDC, the mean annual incidence is 0.3 per 100,000 people. However, for children younger than 5 years old, the incidence is 1.9 per 100,000.35 As many as 6% of older children and adults may present with an appendicitis-like illness with right lower quadrant tenderness, usually as a result of

</table>
| **Salmonella non-typhi** | No; treatment prolongs excretion; does not shorten disease | Infants <3 months old, prolonged illness, chronic GI disease, neoplasms, hemoglobinopathies, HIV, immunosuppression, localized invasive disease (osteomyelitis, abscess, meningitis) or bacteremia | **Susceptibility is known**  
Oral: Amoxicillin 25–50 mg/kg divided every 8 hours  
IV: Ampicillin 200 mg/kg divided every 6 hours  
Oral: TMP-SMX 10 mg/kg divided every 12 hours | **Bacteremia:** Treat for 10 to 14 days  
Local invasive disease:  
Treat for 4 weeks (6 weeks if meningitis) and begin with IV medications  
Aminoglycosides not recommended for invasive disease  
Drug of choice, route of administration, and duration of therapy based on susceptibility of organisms, site of infection, host and clinical response |
| **Salmonella typhi**     | Yes               | All patients with enteric fever  
Delirium, stupor, coma, or shock | **Start with IV medications; change to oral when susceptibility is known**  
Ceftriaxone 100 mg/kg every day or divided every 12 hours or  
Cefotaxime 200 mg/kg divided every 4 to 6 hours (maximum 12 g/day) or  
*Ciprofloxacin 20 mg/kg divided every 12 hours | **Multidrug resistance is common**  
10- to 14-day treatment  
Check susceptibilities  
Azithromycin for uncomplicated disease  
Consider: Dexamethasone IV 3 mg/kg, followed by 1 mg/kg every 6 hours for 48 hours |
| **Shigella species**    | No; usually self-limited but treatment decreases diarrhea and eradicates organism from stool | Severe disease, bacteremia, dysentery, immunosuppression  
Less ill and able to tolerate PO | **IV:** Ceftriaxone 50–100 mg/kg for 5 days or  
*Ciprofloxacin (>17 years old or ceftriaxone contraindicated) 20 mg/kg divided every 12 hours or  
Azithromycin 10 mg/kg for 3 days  
**Oral:** Azithromycin 12 mg/kg for first day, then 6 mg/kg for days 2 to 5 or  
*Ciprofloxacin 20 mg/kg divided every 12 hours for 5 days | **Oral route preferred when possible and disease is not serious**  
TMP-SMX and ampicillin only if isolated strain is susceptible because of high resistance  
Amoxicillin less effective because of rapid absorption from GI tract |
| **Campylobacter jejuni**| Yes               | Usually recommended for all infections; most children will resolve on own | **Oral:** Azithromycin 10 mg/kg for 3 days or  
Erythromycin 40 mg/kg divided every 6 hours for 5 days | **Shorten duration of illness and excretion of organisms and prevent relapse if given early**  
Resistance to fluoroquinolones is frequent |
| **Yersinia enterocolitica** | No | Septicemia or extra intestinal sites of infection; immunocompromised host | **Oral:**  
TMX-SMX 10 mg/kg divided every 12 hours or  
Oral or IV *Fluoroquinolone: Ciprofloxacin 20 mg/kg divided every 12 hours or  
Ceftriaxone 50 to 100 mg/kg divided every day or every 12 hours or  
Cefotaxime 150 to 200 mg/kg divided every 4 to 6 hours (maximum 12 g) | **Usually resistant to penicillin and first generation cephalosporins**  
Antibiotics do decrease the duration of fecal excretion but do not decrease length of diarrhea  
Extraintestinal disease treat for 4 weeks |
| **C. difficile**         | Yes               | Symptomatic patients  
Severe disease, underlying intestinal tract disease, and those who don’t respond to oral metronidazole use vancomycin | **Stop antimicrobial therapy**  
Oral or IV: Metronidazole 30 mg/kg divided every 6 hours for at least 10 days (maximum dose 2 g/day) or

*Fluorquinolone: Tetracycline is not recommended in children younger than 8 years old because of teeth staining, but the benefit of using the drug may outweigh the risk of teeth staining. Each case is considered separately. Ciprofloxin recommended for greater or equal to 17 years unless benefits outweigh the risks.

G1, Gastrointestinal; HIV, human immunodeficiency virus; HUS, hemolytic-uremic syndrome; IM, intramuscular; IV, intravenous; PO, per os (by mouth); RLA, resource limited area; STEC, Shiga toxin–producing E. coli; TMP-SMX, trimethoprim-sulfamethoxazole.

Reactive mesenteric adenitis. Antibiotics are indicated for the immunocompromised patient with enterocolitis and in cases of septicemia or extraintestinal infections. Isolates are often resistant to first-generation cephalosporins and most penicillins.

Thought to be brought on by the change in the gut flora from antibiotics. C. difficile infections among hospitalized children have been increasing since 1997. However, there are an increasing number of cases in children who have not been hospitalized or received antibiotics. C. difficile infections cause a spectrum of illnesses ranging from asymptomatic to watery diarrhea to pseudomembranous colitis. Clinical illness is rare before 12 to 24 months old. Asymptomatic infants can be colonized with C. difficile; carriage rates average 37% to 50% for neonates, 30% for infants 1 to 6 months old, 14% for infants 6 to 12 months old, and by age 3 years old the rate of colonization is similar to that of nonhospitalized adults (<3%). Thus, the presence of C. difficile toxin cannot be assumed to be a causative agent in young children. C. difficile should be considered in children 1 to 3 years old, but only after other causes of diarrhea (particularly viral) are excluded. Endoscopic findings of pseudomembrane and friable rectal mucosa are sufficient to diagnose C. difficile at any age. This is helpful when trying to determine if a child younger than 3 years old is colonized or has disease. The endoscopic findings are diagnostic of disease. Complications include toxic megacolon and intestinal perforation. Severe or fatal disease is more common in neutropenic patients with leukemia, infants with Hirschsprung’s disease, and patients with inflammatory bowel disease.

See Tables 172.3 and 172.4 for presentation and associated characteristics and treatment recommendations for Clostridium perfringens, Staphylococcus aureus, V. cholera, and Vibrio parahaemolyticus.

E. coli, part of the normal flora in the lower gastrointestinal tract, includes five species types recognized to cause acute diarrheal disease. The enterohemorrhagic E. coli (EHEC) strain is also known as Shiga toxin–producing E. coli (STEC); E. coli O157:H7 is the prototype and most virulent of the EHEC. Outbreaks have been linked to ground beef, petting zoos, contaminated apple cider, raw fruits and vegetables, and ingestion of water in recreational areas. The infectious dose is low, and person-to-person transmission can occur. There are an estimated 265,000 cases of STEC infections per year; 36% are caused by E. coli O157. HUS, the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency, is a serious complication of EHEC infection and occurs in up to 15% of children with E. coli O157:H7. The overall incidence of HUS caused by a diarrheal pathogen (usually STEC) is estimated to be 2.1 cases per 100,000 persons per year, with a peak incidence in children younger than 5 years old (6.1 cases per 100,000 per year). HUS typically develops as diarrhea that is resolving, usually 7 days but up to 3 weeks after the onset of the illness. Patients often present with pallor, weakness, irritability, and oliguria or anuria. Patients with HUS can develop neurologic complications, such as seizures, coma, and cerebral vessel thrombosis. Approximately 50% of patients who have HUS will require dialysis, and 3% to 5% die. Patients with white blood cell counts greater than 20,000, hematocrit less than 23%, and oliguria are at increased risk for poor outcome. A serious risk posed by hemorrhagic colitis is the rapid loss of fluids, which can cause electrolyte abnormalities and result in poor perfusion, leading to end-organ damage. Patients should receive adequate amounts of intravenous (IV) fluids (or by mouth if able to take in enough) to restore intravascular volume (monitor urine output, capillary refill time, blood pressure, pulse, and mental status), and electrolyte abnormalities should be corrected. Fluids should be continued and ongoing losses replaced. Consideration of admission to the hospital with fluid resuscitation, ongoing monitoring of electrolytes, complete blood cell count, blood urea nitrogen (BUN), and creatinine are imperative.

Controversy exists about the indications for antibiotic treatment of E. coli diarrhea. Early data indicated that antimicrobials offer no substantial benefit and may increase the risk for development of HUS. In addition, in vitro studies have shown that sub-inhibitory antibiotic concentrations can increase toxin production. Most recently, in 2012, a study showed an increased risk of developing HUS if a child with STEC is treated with antibiotics (36% versus 12%, P = 0.001). This risk was seen across all antibiotic classes. Therefore, we recommend that empirical antibiotics should not be administered because of the potential risk of HUS—except in cases when a child is extremely ill or in septic shock.

Protozoa

Protozoa can also cause diarrhea in children but are responsible for less than 1% of all cases of acute infectious diarrhea in the United States (Tables 172.5 and 172.6). The most common

_E. histolytica_ can be found worldwide but is more prevalent in the lower socioeconomic population and in developing countries, where the prevalence of amebic infection may be as high as 50% in some communities. Symptoms can become chronic and may mimic inflammatory bowel disease. Complications include fulminant colitis, toxic megacolon, and ulceration of the colon and perianal area, rarely with perforation. Complications are more common in patients treated inappropriately with corticosteroids or antimotility drugs. Ultrasonography, computed tomography, and magnetic resonance imaging can identify liver abscesses and other extraintestinal sites of infection. Follow-up stool examination is recommended after completion of therapy, because complete eradication of intestinal infection is difficult. Asymptomatic household members with stools positive for _E. histolytica_ should also be treated. 45

See Tables 172.2, 172.3 and 172.5 for common signs and symptoms of the different viruses, bacteria, and protozoa discussed.

**Complications**

The complications of acute diarrheal illness are reflected primarily in abnormalities of fluid, electrolytes, and acid-base status and in systemic involvement (bacteremia, osteomyelitis, polyarthritis,
Diagnostic Strategies

Acute diarrhea in children usually results in self-limited mild disease; it can, however, cause significant fluid and electrolyte abnormalities with serious consequences. Indications for medical evaluation of children with diarrhea have been proposed (Box 172.3). The principal goals of the ED evaluation are to identify and to correct fluid, electrolyte, acid-base, and nutrient deficits that may result from vomiting, diarrhea, or decreased oral intake and to determine which children would benefit from prolonged management.

Children who present with mild to moderate disease often require no diagnostic testing and can often rehydrate orally. Children assessed to have moderate to severe dehydration from acute diarrhea with or without vomiting requiring IV fluids should have baseline serum electrolyte levels, bicarbonate, urea/creatinine, and glucose concentration assessed. Studies evaluating the use of laboratory tests to estimate hydration status have found testing helpful only when results are markedly abnormal, with no specific test definitive for dehydration. Children who are critically ill or hemodynamically unstable should have a fingerstick blood glucose and serum electrolytes measured.

Testing for fecal leukocytes may be useful to support a diagnosis of invasive disease and should be considered in children with diarrhea who are febrile or have mucus or blood in their stool. Many children with acute diarrhea caused by Salmonella or Shigella organisms will have fecal leukocytes in the stool. Fecal leukocytes are also found in patients with Campylobacter organisms, Y. enterocolitica, invasive E. coli, and V. parahaemolyticus. Although a negative test does not rule out invasive disease, a positive test (more than five fecal leukocytes per high power field) increases the likelihood of an invasive pathogen and should be followed with a stool culture.

Stool culture is not indicated in most cases of uncomplicated AGE. Stool cultures should be obtained when needed to guide specific therapy, hospitalization, or infection control measures. Stool cultures should also be considered in patients with systemic involvement or underlying chronic medical conditions, if the illness involves dysenteric features, or if it lasts longer than 2 weeks. Many hospital laboratories do not include testing for E. coli O157:H7 or Y. enterocolitica in their routine stool culture; thus the emergency clinician must order these tests separately. According to the CDC, all stools submitted for testing for Salmonella, Shigella, and Campylobacter (routine stool culture) should be cultured for E. coli O157:H7. These stools should also be simultaneously assayed for non-O157 STEC with tests that detects the Shiga toxins or the genes encoding these toxins. In immunosuppressed patients, patients with chronic disease, infants younger than 3 months, or children with possible bacteremia or localized invasive disease, a complete blood count, stool studies, blood and urine cultures, chest x-ray, and lumbar puncture should be considered.

For patients with more than 2 weeks of watery diarrhea, consider sending stool for enzyme-linked immunoassay for rotavirus and ova and parasites in those with a history of travel to an endemic area.

Consideration of Differential Diagnoses

Most children with diarrhea or vomiting have a relatively benign cause of their illness. However, other, more sinister diagnoses should be considered and ruled out. A few disorders causing diarrhea may be life-threatening in children: intussusception, HUS, pseudomembranous colitis, appendicitis, toxic megacolon, and in very young infants, the congenital secretory diarrheas. See Tables 172.7 and 172.8 for other conditions that may cause vomiting and diarrhea.

Management

The American Academy of Pediatrics (AAP), The European Society of Pediatric Gastroenterology and Nutrition, and the WHO all recommend oral rehydration solution as the treatment of choice for children with mild to moderate dehydration (see the Dehydration section). In addition to fluid resuscitation, the

**Indications for Medical Evaluation of Children With Acute Diarrhea**

- Young age (eg, <6 months old or weight <8 kg)
- History of premature birth, chronic medical conditions, or concurrent illness
- Fever to ≥38°C for infants <3 months or ≥39°C for children 3 to 36 months old
- Visible blood or mucus in stool
- High output, including frequent and substantial volumes of diarrhea
- Persistent vomiting
- Caregiver’s report of signs consistent with dehydration (eg, sunken eyes or decreased tears, dry mucous membranes, or decreased urine output)
- Change in mental status (eg, irritability, apathy, or lethargy)
- Suboptimal response to oral rehydration therapy (ORT) already administered or inability of the caregiver to administer ORT

study, which was carried out in three Italian pediatric centers, showed that *L. reuteri*, taken together with a standard oral rehydration solution, significantly reduced the duration of watery diarrhea compared with placebo (2.1 ± 1.7 days versus 3.3 ± 2.1 days, P < 0.05). On days 2 and 3 of treatment, watery diarrhea persisted in 82% and 74% of the placebo and 55% and 45% of the *L. reuteri* recipients. Studies have also reported that *L. rhamnosus* is the most effective at doses greater than 10^10 colony-forming units. Probiotics also seem to be more effective when given early in the course of diarrhea and are most helpful for otherwise healthy infants and young children with watery diarrhea secondary to viral gastroenteritis but not invasive bacterial infections. The European Society of Gastroenterology, Hepatology, and Nutrition, the National Institute for Health and Clinical Excellence, and the AAP all agree that when used alongside rehydration therapy, probiotics appear to be safe and have clear beneficial effects in shortening the duration of and reducing stool frequency in acute infectious diarrhea. More research is needed to determine appropriate doses for different strains of probiotics.

Zinc deficiency is common in developing countries and occurs in most parts of Latin America, Africa, the Middle East, and south Asia. During the past 10 to 15 years, studies have shown that zinc supplementation given to children living in developing countries has decreased the duration and severity of diarrhea illness. A recent Cochrane review looked at 24 published studies and found zinc supplementation may be effective in reducing the duration of diarrhea in children older than 6 months in areas where zinc deficiency and moderate malnutrition is prevalent. The WHO recommends zinc supplementation (10 to 20 mg/day for 10 to 14 days) for all children younger than 5 years old with AGE, although few data exist to support this recommendation for children in developed countries.

### Disposition

Most cases of childhood diarrhea can be managed on an outpatient basis by continuing breast-feeding, routine formula, or diet specific for age. Supplemental maintenance electrolyte solutions may be given or recommended to purchase over the counter. Before discharge from the ED, careful and specific instruction about the signs and symptoms of expected improvement or complications should be given to the parents or caregiver. Instructions should address proper hygiene and handwashing techniques to prevent others from contracting the illness. Follow-up by the patient’s primary care physician should be timely and address concerns of worsening of the condition and potential complications. Hospitalization should be considered in children at high risk for complications: infants, especially those younger than 3 months old, very-low-birth-weight infants, and children with chronic medical problems, children with electrolyte abnormalities who require IV repletion, children with severe dehydration, and children with dysentery. Hospitalization may also be warranted in cases of protracted vomiting, diarrhea with losses in excess of fluid administration, worsening clinical status despite therapy, presence of an underlying condition that would complicate therapy, or suspected systemic involvement. Very-low-birth-weight infants, because of low physiologic reserve and immature immune system, are at the highest risk for complications of AGE in the first year of life.

### DEHYDRATION

#### Perspective

Dehydration, defined as a decrease in total body water, is a common complication seen in the ED. In severe cases, early detection and rehydration are vital to prevent progression to tissue
hypoperfusion and end-organ damage. Oral rehydration for mild to moderately dehydrated children has been identified as one of the American College of Emergency Physicians’ Choosing Wisely Campaign’s top five ways to improve the value of emergency medicine encounters. Dehydration (loss of free water) can be distinguished from volume depletion (decrease in effective circulatory volume), but because most relevant research does not make this distinction, the terms are often used interchangeably. Broadly speaking, dehydration occurs by three general mechanisms: (1) decreased intake (eg, stomatitis), (2) increased output (eg, diarrhea and diabetes), and (3) increased insensible losses (eg, fever). Most commonly, dehydration in children is due to volume losses from AGE, but many principles discussed here apply to other disease processes leading to dehydration.

Principles of Disease

Anatomy and Physiology

The average adult male and female bodies are comprised of approximately 60% and 50% water, respectively. Total body water is divided between the extracellular ($\frac{2}{3}$) and intracellular compartments ($\frac{1}{3}$). The extracellular compartment is further divided into interstitial fluid ($\frac{2}{3}$) and plasma ($\frac{1}{3}$). Interstitial fluid serves as a reservoir to replenish intravascular plasma volume in hypovolemia. Because infants excrete far more water than adults per body weight (100 mL/kg versus 40 mL/kg daily), they require far more water per body weight to maintain homeostasis. As a result, infants and children are more vulnerable to rapid volume depletion from decreased water intake or increased output.

Pathophysiology

Isonatremic volume depletion (130 to 150 mEq/L) is the most common form of volume depletion and results from relatively equal losses of sodium and water from the extracellular space and therefore intravascular volume. There is no change in body fluid tonicity or redistribution of fluid between the extracellular and intracellular fluid spaces. Gastrointestinal fluid loss, with or without decreased intake or increased urine loss, is the most common cause. Hyponatremic volume depletion (<130 mEq/L) results from sodium loss in relative excess of free water loss. Free water then moves intracellularly from the extracellular space to maintain osmolarity, leading to a decrease in intravascular volume and potential hemodynamic compromise. This type of volume depletion is often caused by gastrointestinal fluid loss replaced by free water, although other etiologies, such as syndrome of inappropriate antidiuretic hormone secretion (SIADH), should be considered. Infants and children with hyponatremic volume depletion are often more ill-appearing than fluid losses would indicate. Hypernatremic volume depletion (>150 mEq/L) arises from the loss of relatively more free water than sodium and is observed less commonly than hyponatremic or isonatremic dehydration. This can occur if a child with diarrhea is given hypertonic fluid (eg, soup, improperly mixed formula, water with baking soda) to replace fluid losses, or if the illness is complicated by excessive insensible losses from fever of hyperventilation. Intracellular free water shifts to the extracellular compartment to maintain osmolarity, resulting in relatively preserved intravascular volume, and often underestimation of volume depletion. Hypernatremic dehydration is usually associated with at least a 10% free water deficit. Both hyponatremic and hypernatremic dehydration can lead to severe CNS effects: cerebral edema in the case of hyponatremic dehydration due to free water movement into neurons, and cerebral shrinkage in the case of hypernatremic dehydration due to free water movement out of neurons. Similarly, rapid correction of either condition can cause dangerous fluid shifts across the blood-brain barrier and should be avoided.

Metabolic acidosis often accompanies pediatric dehydration due to AGE through several mechanisms: bicarbonate loss in the stool, starvation causing ketone production, decreased tissue perfusion leading to anaerobic metabolism and lactic acid production, and decreased hydrogen ion excretion from poor renal perfusion. For the majority of patients, the acidosis is easily reversed by oral or parenteral volume replacement.

Clinical Features

The severity of dehydration is usually measured as the acute weight (presumably fluid) loss as a percentage of pre-illness total body weight. Dehydration of 3% to 5% or more is considered significant and can often be identified by history and physical examination (Table 172.9). Because pre-illness weights are generally not available or reliably reported, the clinician should rely on historical information and physical examination findings to assess the severity of dehydration. Parental reports of decreased oral intake, urine output, and tear production are of significant value, with good sensitivity in detecting dehydration. In a child who is dehydrated, initial physical examination may reveal an activity level lower than expected for age. The child may also appear weak or lethargic. If the fontanel is still open, it may be sunken. The eyes may appear sunken and the mucous membranes dry. However, if the child has recently had something to drink, the mucous membranes may falsely appear moist. Tachycardia and hyperpnea may be present. The skin over the trunk should be tented (Fig. 172.1) (suggesting hyponatremia) or a doughy texture (suggesting hypernatremia). The three most useful signs to determine dehydration of more than 5% are prolonged capillary refill time, abnormal skin turgor, and abnormal respiratory pattern. However, clinical signs and symptoms of dehydration are variable and often subtle, and determining the severity of dehydration is an ongoing challenge for emergency clinicians. Because individual signs are often inadequate for accurately diagnosing dehydration and estimating severity, most recent research has

Adapted from Barkin RM, Rosen P: Emergency pediatrics, ed 5, St Louis, 1999, Mosby.
focused on noninvasive methods of dehydration assessment, including clinical scoring systems, bedside ultrasound, and laboratory testing.67

Clinical scoring systems have been developed by combining historical features and examination findings in an effort to better predict the presence and severity of pediatric dehydration. The Clinical Dehydration Score (CDS) and the Gorelick scale (Table 172.10) are the most widely used and well-studied.58,59 In 2015, a meta-analysis found both the CDS and Gorelick scale improve diagnostic accuracy over unstructured physician assessment. However, with only approximately 80% accuracy, neither can definitively rule in or out dehydration in infants and children.57

Diagnostic Strategies

The role of bedside ultrasound in the assessment of volume depletion in children is uncertain. Although inferior vena cava (IVC) collapsibility has not been shown to correlate with hydration status, an IVC to aorta ratio of 0.8 or less has been found to improve diagnostic accuracy.60,61 However, because the test characteristics of bedside ultrasound (sensitivity 67% to 86%, specificity 56% to 71%) offer little to no advantage over clinical scores, and correlation between IVC to aorta ratio and intravascular volume depletion have been questioned, routine application of bedside ultrasound for this purpose is not recommended.57,62

Laboratory tests are of little diagnostic value in the mildly dehydrated child, but they may be helpful in the severely dehydrated or ill-appearing child to assess etiology, severity, and complications of dehydration. A serum electrolyte panel and BUN, serum creatinine, and blood glucose level are most likely to be clinically useful. Sodium concentration is important in identifying isonatremic, hyponatremic, and hypernatremic states for appropriate choice of therapy. A low serum bicarbonate level may indicate loss of bicarbonate loss in the stool or may reflect poor tissue perfusion. Children with dysentery, characterized by fever, bloody stools, and abdominal cramping, should have BUN and serum creatinine concentrations measured and stool culture specimens sent and examined for *E. coli* O157:H7 to identify potential cases of HUS. Serum glucose level is important because hypoglycemia is not uncommon in young children with AGE, and this test may help identify children with previously undiagnosed fatty acid oxidation disorders or other inborn errors of metabolism (eg, galactosemia). Urine specific gravity and ketones are neither sensitive nor specific and should not be used in the assessment of pediatric dehydration.

Consideration of Differential Diagnoses

Most commonly, dehydration in children results from diarrhea and vomiting caused by infectious gastroenteritis. Table 172.11

### BOX 172.4

**Principles of Appropriate Treatment of Children With Diarrhea and Dehydration**

Oral rehydration solutions should be used for rehydration. Oral rehydration should be performed as rapidly as possible. Unrestricted diet is recommended as soon as dehydration is corrected. For breast-fed infants, nursing should be continued. For formula-fed infants, diluted formula is not recommended. Special formula is not necessary. Additional oral rehydration solution should be administered for ongoing diarrheal losses.

In the last several years, ondansetron has become a useful adjunct in the treatment of AGE in the ED. Ondansetron, a selective 5-hydroxytryptamine type 3 receptor antagonist, acts at chemoreceptors in the peripheral and CNS to alleviate nausea. Ondansetron has been shown in numerous well-designed studies in children to reduce episodes of vomiting in the ED, improve oral intake in the ED, reduce the need for IV fluid rehydration, and reduce admissions.

### Management

#### Oral Rehydration Therapy

Oral rehydration therapy (ORT) is a safe and effective treatment of infants and children with mild to moderate dehydration. ORT may be instituted even if the patient continues to vomit or has diarrhea. Children with severe dehydration, shock, lethargy, acute abdomen, suspected intestinal obstruction, sodium derangement, or significant underlying illness should be identified by means of a thorough history and physical examination and laboratory tests and be excluded from ORT. Some of these principles are illustrated in Box 172.4.

The ORT period in the ED may span 4 to 8 hours and provides an opportunity to educate the family in skills of evaluating and treating childhood diarrhea. A number of oral rehydration solutions have been shown to be effective. The main ingredients are water, glucose, sodium chloride, and bicarbonate in various concentrations. In most situations, rehydration can be accomplished without the risk of causing hyponatremia or hypernatremia.

In infants and children with minimal dehydration, treatment should be directed at maintaining hydration and nutrition with an age-appropriate diet. Fluid intake should be increased, or oral rehydration solution can be administered to cover maintenance needs and to replace losses. Losses can be replaced at 10 mL/kg for each stool and 2 mL/kg for each emesis. Diet should not be restricted.

Children with mild to moderate dehydration should have their estimated fluid deficit replaced, often started in the ED and continued at home. The volume of ORT is calculated in the following manner:

1. Estimate the degree of volume depletion as mild or moderate with information from the history, clinical signs, and physical examination findings (see Tables 172.9 and 172.10).
2. Calculate the desired volume of oral rehydration solution as 30 to 50 mL/kg for mild (3% to 5%) and 60 to 80 mL/kg for moderate (6% to 9%) volume depletion.
3. Administer 25% of the volume of oral rehydration solution to be replaced each hour for the first 4 hours.
4. Continue to replace ongoing losses as described above.
5. Monitor progress hourly and reevaluate frequently.

This technique requires that the ED have the facilities and personnel to observe and monitor the patient for an extended time to determine the success or failure of ORT. The parent or other caregiver must be taught to administer ORT. Nursing personnel should instruct the parent in observation skills, methods of administration of the fluid, and types of fluid that are considered appropriate for children with vomiting and diarrhea. During the monitoring period, a child who is unable to tolerate intake of the prescribed volume of fluid at the expected rate should receive IV fluids. It is important to determine whether the failure is the result of the child’s inability to ingest the fluid, excessive fluid loss through vomiting or diarrhea, or poor technique or motivation on the parent’s part. It usually is possible to maintain the fluid administration rate in children who continue to vomit by administering small volumes frequently. This may require, for instance, use of a spoon or syringe to slowly drip the fluid by hand. Some success has been obtained with the use of nasogastric tubes. The patient is reassessed at the end of the first few hours. If the clinical examination indicates adequate volume repletion, the child may be discharged home with further specific instructions for parents about maintenance fluid requirements with oral rehydration solution. If the child still exhibits mild or moderate volume depletion on clinical examination but no deterioration in status has occurred, another 2- to 4-hour trial may be warranted. If the child is unable to ingest the appropriate volume to keep up with ongoing losses, or if volume repletion is not adequate at the end of 8 hours, IV therapy and admission are required.

In the last several years, ondansetron has become a useful adjunct in the treatment of AGE in the ED. Ondansetron, a selective 5-hydroxytryptamine type 3 receptor antagonist, acts at chemoreceptors in the peripheral and CNS to alleviate nausea.

Intravenous Therapy

Some dehydrated children brought to the ED may not qualify for ORT, and others may fail to improve with ORT. These patients include those with shock, severe dehydration, increasing deficit or clinical deterioration during ORT, intractable vomiting, hypoglycemia, or electrolyte derangements.

Patients are evaluated in accordance with their immediate (emergency phase), short-term (repletion phase), and long-term (early refeeding phase) needs. During the emergency phase, the aim of fluid resuscitation is to restore circulatory volume. Fluid needs to be administered rapidly to prevent tissue hypoperfusion, end-organ damage, and death. During the repletion phase, fluid and electrolyte derangements are reversed, and ongoing losses are replaced. This phase lasts 24 hours. In the early refeeding phase, long-term needs are addressed in the next few days, during which the body recovers fluid, electrolyte, and nutritional homeostasis. Immediate and short-term therapies are initiated in the ED, with subsequent phases carried out in the inpatient setting or at home.
as managed by the primary care physician. In clinical practice, this algorithm represents a continuum of care and not three distinct, separate phases. Monitoring of serum electrolyte, BUN, and blood glucose concentrations is indicated for patients receiving IV fluid therapy.

Emergency Resuscitation Phase. Rapid reexpansion of the intravascular space is the goal of immediate resuscitation and can be achieved with an isotonic crystalloid solution. Administration of 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) intravenously at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. In critical situations, intraosseous routes should be used if venous access is not immediately available. Patients should be reevaluated periodically, and those with excessive deficits should receive repeated boluses of 20 mL/kg until clinical improvement occurs. Signs of recovery include normalization of blood pressure measurements, improvement of mental status, improvement of tachycardia and capillary refill time, and production of urine. Volume requirements greater than 60 mL/kg without signs of improvement warrant investigation for other conditions, such as septic shock, hemorrhage, capillary leak with third-space fluid sequestration, and toxic shock.

A rapid determination of serum glucose is important. Children require glucose as an energy substrate and often have marginal stores available in illnesses. If the serum glucose concentration is low (<50 mg/dL), dextrose 0.25 to 0.5 g/kg should be rapidly administered intravenously or intraosseously. Glucose can be administered per the “rule of 50,” whereby the percent dextrose multiplied by the number of mL per kilogram equals 50. For neonates, a 10% dextrose solution should be given at approximately 5 mL/kg. Children 1 month old to approximately 8 years old or 25 kg should be given 2 mL/kg of 25% dextrose. In children older than 2 years old, 1 mL/kg of 50% dextrose can be used. Glucose levels should be monitored (every 30 to 60 minutes until stable) to ensure improvement and to identify ongoing needs. Repeated episodes of hypoglycemia should raise concern for sepsis, fatty acid oxidation defects, or other inborn errors of metabolism.

Dehydration due to AGE in children often leads to metabolic acidosis and ketosis, in part due to reduced carbohydrate intake leading to free fatty acid breakdown. It has been hypothesized that the addition of dextrose to initial IV rehydration fluids in moderately to severely dehydrated children will stimulate insulin release, reduce free fatty acid breakdown and ketone production, and reduce ketone-induced nausea and vomiting. This theory has been tested in small studies and produced mixed results. Levy and colleagues conducted a randomized controlled trial of 5% dextrose in normal saline compared with normal saline for initial fluid resuscitation in 188 children. There was no difference in the primary outcome of hospitalization rates between groups, but they did find a greater reduction in serum ketone levels in the dextrose group. Further research focusing on patient-oriented outcomes is needed to determine whether dextrose should be included in the optimal rehydration regimen for moderately to severely dehydrated children requiring IV hydration.

Repletion Phase. Appropriate fluid therapy for the patient should be determined after immediate resuscitation. Some patients may tolerate ORT after initial resuscitation; others may require ongoing parenteral hydration with 5% dextrose in half-normal normal at a weight-appropriate maintenance volume (Table 172.12), compensating for ongoing losses (10 mL/kg and 2 mL/kg for each diarrhea and vomiting episode, respectively). Potassium may be added to maintenance fluids once urine output is established and serum potassium levels are within a normal range. Overly rapid correction of serum sodium levels (>0.5 to 1 mEq/hr or >12 to 24 mEq/day) can lead to central pontine myelinolysis in hyponatremia and cerebral edema in hypernatremia. Neurologic status and serum sodium concentration should be closely monitored and the amount of sodium content of repletion fluid adjusted to maintain a slow correction. Ongoing sodium losses should also be replaced. In addition to oral, IV, intraosseous, and nasogastric routes of fluid delivery, hyaluronidase-facilitated subcutaneous hydration (hypodermoclysis) offers yet another alternative for treatment of dehydration. Hyaluronidase breaks down hyaluronic acid, an extracellular matrix that holds body tissues together and would otherwise prevent subcutaneous fluid from diffusing into tissues and capillaries. Early studies of this method have found it to be safe, quick, cost-effective, and non-inferior to IV hydration in terms of volume of fluid infused in the ED. While awaiting further investigation into its widespread use in varied clinical settings, subcutaneous hydration should be considered in mildly to moderately dehydrated children who are unable to tolerate oral fluids and who have difficult IV access.

Hospital-Acquired Hyponatremia. IV rehydration can lead to hyponatremia in children. This rare complication can lead to significant neurologic morbidity, including seizures, coma, and brain herniation or even death; children receiving IV fluids should have their neurologic status closely monitored. For acute hyponatremia to occur, two conditions have to be met: (1) an exogenous source of free water must be available, and (2) secretion of antidiuretic hormone must occur. For this reason, isotonic saline (rather than hypotonic saline) is the preferred IV fluid in hospitalized children.

Disposition

Children with severe dehydration, intractable vomiting, inability to maintain oral hydration, severe metabolic acidosis or sodium derangement, or whose caregivers are unable to provide adequate care at home should be hospitalized. Observation status is often suitable for severely dehydrated children showing signs of improvement during their ED course.

### Identification of Pathogen
- Stool studies are not indicated in most uncomplicated cases of acute gastroenteritis (AGE). Exceptions are those cases in which specific treatment, specific prophylaxis, or health precautions are required, or in which the patient has systemic involvement, underlying medical complications, or the illness involves dysenteric features.
- Antibiotics are not required for most cases of uncomplicated acute bacterial enteritis. Antibiotics are recommended routinely for *Campylobacter, C. difficile, Giardia intestinalis*, and *E. histolytica*. Antibiotics can be considered for *Cryptosporidium*, traveler’s diarrhea, and *Shigella* (because antibiotics have been shown to decrease diarrhea and eradicate organisms in the stool).
- Patients with Shiga toxin–producing *E. coli* (STEC) should not empirically receive antibiotics, because they may increase the risk of hemolytic-uremic syndrome (HUS).
- Testing for fecal leukocytes is a useful initial test because it may support a diagnosis of invasive disease. This test should be considered in children with diarrhea who are febrile or have mucus or blood in the stool. If the test result is positive, stool culture is indicated to further guide management.

### Oral Rehydration
- Most patients with mild to moderate dehydration can be treated with oral rehydration therapy (ORT). Resumption of feeding with age-appropriate diets should begin as soon as vomiting subsides. Routine fasting with infectious diarrhea is not recommended.

### Dehydration Assessment
- The degree of volume depletion is estimated from the history and physical examination findings. The desired volume of oral rehydration solution is calculated as 30 to 50 mL/kg for mild dehydration and 60 to 80 mL/kg for moderate dehydration; 25% of the volume of oral rehydration solution is to be replaced every hour (100% over 4 hours). Continue to replace ongoing losses with 10 mL/kg for each diarrheal stool and 2 mL/kg for each vomiting episode.

### Severe Dehydration
- In severe dehydration, 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) given intravenously at a rapid rate should reverse signs of shock within 5 to 15 minutes. Repeated boluses of 20 mL/kg are indicated until clinical improvement occurs, but volume requirements greater than 60 mL/kg without signs of improvement suggest other conditions, such as septic shock, hemorrhage, capillary leak with third-space fluid sequestration, and heart failure.

CHAPTER 172: QUESTIONS & ANSWERS

172.1. A 5-month-old male infant presents in December with a 1-day history of fever to 38.3°C, emesis, and multiple episodes of foul-smelling, greenish, watery diarrhea. Physical examination reveals an awake but tired baby with a sunken fontanel, dry mucous membranes, decreased skin turgor, and irritated skin in the diaper area. What is the most likely cause of this patient’s gastroenteritis?
A. Astrovirus
B. Escherichia coli
C. Norwalk virus
D. Rotavirus
E. Salmonella spp.

Answer: D. The child described most likely has diarrhea caused by rotavirus. Rotavirus is the most common cause of acute diarrheal illnesses in infants and toddlers. Norwalk virus and E. coli are not common causes of diarrhea in young infants. Astrovirus is a cause of diarrhea in children younger than 4 years old, but most of the infections are asymptomatic. Salmonella spp. also causes diarrhea in infants, but it is much less common.

172.2. For which of the following patients should the emergency clinician not obtain diagnostic testing of the stool?

A. 1-month-old with fever to 38°C with bloody diarrhea
B. 8-month-old with sickle cell disease with fever and diarrhea
C. 12-month-old, well-appearing child with 2 days of watery diarrhea
D. 2-year-old with nephrotic syndrome on prednisone with diarrhea and fever for 3 days
E. Community outbreak of diarrhea

Answer: C. Most children with uncomplicated gastroenteritis or acute diarrhea do not need laboratory studies. Stool cultures are useful and important to obtain in febrile infants and children with blood in their stools, in community outbreaks, and in the immunosuppressed.

172.3. A 4-year-old child presents with moderate dehydration from gastroenteritis. He is still actively vomiting. Which of the following statements regarding this patient’s rehydration is correct?

A. A nasogastric tube should be placed for rehydration.
B. Oral rehydration should not be started.
C. Oral rehydration success can be determined in 2 or 3 hours.
D. Oral rehydration target volume is 80 mL/kg.
E. Target oral rehydration volume should be administered over 2 hours.

Answer: D. Oral rehydration target volume is 80 mL/kg.

172.4. A 9-year-old child with a history of sickle cell disease presents for evaluation of fevers, diarrhea, and vomiting. The parents say the patient has not had a sickle cell crisis in almost a year. On examination, the vital signs are stable and the child is nontoxic appearing with mild dehydration. His abdominal examination is benign. In addition to rehydration, which of the following would be the most appropriate management and disposition for this child?

A. Obtain blood cultures and admit for observation.
B. Obtain cultures (stool and blood), begin antibiotics, continue hydration, and admit for observation.
C. Obtain electrolytes; and if he has a normal bicarbonate level, then discharge home.
D. Perform a stat rotavirus assay; and if negative and patient tolerates oral intake, then discharge home.
E. Provide oral rehydration therapy (ORT); and if successful, then discharge home.

Answer: B. Patients with sickle cell disease are more susceptible to Salmonella infections and are at increased risk for complications. It has been shown that giving antibiotics to patients with nontyphoidal Salmonella has been ineffective in shortening the duration of symptoms and prolonging the carrier state. Therefore antibiotics are generally not recommended for asymptomatic cases or for uncomplicated cases. However, antibiotic treatment is indicated in infants younger than 3 months old or those with complications, such as failure to improve within 5 to 7 days; bacteremia; focal infection in the central nervous system (CNS), bone, joint, kidney, or pericardium; or those with immunosuppressive conditions, hemoglobinopathies, malignant neoplasms, human immunodeficiency virus (HIV), or chronic gastrointestinal disease. The recommended antibiotics are for unknown susceptibility or in areas of high resistance to use ceftriaxone or cefotaxime until susceptibility is known. Ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX) may also be effective, but they should only be used in high-risk individuals once susceptibility is known.
Genitourinary and Renal Tract Disorders

PRIAPISM

Principles

Priapism is the engorgement of the dorsal corpora cavernosa, resulting in dorsal penile erection lasting more than 4 hours (Fig. 173.1). Low-flow (also called anoxic or veno-occlusive) priapism is the most common form and occurs secondary to decreased venous outflow. Stuttering priapism is recurrent episodes of ischemic priapism, most lasting less than 4 hours. Episodes may increase in frequency and duration, with potential to develop into a major episode. High-flow (also called arterial or congenital) priapism is usually painless and is typically associated with trauma to the cavernosal artery, congenital anomaly, or fistula, resulting in excessive inflow of arterial blood and corporal engorgement. Oxygenation is maintained and emergent intervention is not typically necessary. Neurogenic priapism is not related to blood flow occlusion.

Clinical Features

Priapism can present at any age, including the neonate. Sickle cell disease (SSD) is responsible for most cases in children, with nearly 50% of all males with SSD having at least one episode of priapism. Other causes of priapism include malignancy, immunosuppressive disorders, medications, drugs of abuse, and toxin exposure. Complications include penile fibrosis, urinary retention, and impotence.

Diagnostic Considerations

Diagnostic Testing

Priapism is a clinical diagnosis. A complete blood count (CBC) and reticulocyte count are useful in sickle cell cases and hemoglobin electrophoresis if the hemoglobin S status is unknown. Rarely, a CBC may reveal an undiagnosed leukemia. In undifferentiated cases, a corporal cavernosal blood gas may differentiate the type of priapism, ischemic versus nonischemic, and color duplex ultrasonography can evaluate intracorporal blood flow (Table 173.1). Angiography may localize the site of arterial bleeding for embolization in high-flow priapism.

Differential Diagnoses

The differential diagnosis for priapism in children differs from that in adults. Penile erection from sexual arousal, erectile dysfunction medication, urethral foreign bodies, Peyronie’s disease, spinal cord injury, and penile implants occur more commonly in adults than children.

Management

Ischemic or low-flow priapism is a compartment syndrome of the penis and requires emergent treatment. Management includes hydration, pain control, relief of urinary obstruction, and treatment of underlying conditions. Local anesthesia by a dorsal nerve block or ring block should be performed prior to aspiration, followed by intracavernous injection (ICI) of sympathomimetic drugs (Fig. 173.2). Phenylephrine is the preferred agent, but epinephrine or ephedrine may also be used.

To perform aspiration, place an 18-gauge angiocatheter (smaller in young children) percutaneously into the lateral aspect of the penile shaft entering the corpus cavernosum. Aspirate and evacuate blood from the corpora cavernosa. Next, irrigate with normal saline (NS) or in combination with an ICI of an α-adrenergic sympathomimetic agent. Instill 1 mL of dilute phenylephrine (100–500 µg phenylephrine/mL of NS) into the corpus cavernosum every 3 to 5 minutes for up to 1 hour. If these measures fail to resolve the priapism, emergent urologic consultation should be obtained for possible surgical shunt placement. Prolonged episodes (>48 hours) are associated with a high likelihood of erectile dysfunction, irrespective of clinical management.

Treatment in nonischemic priapism is observation, because over two-thirds of cases resolve spontaneously. Refractory cases may require cavernosal artery embolization or arterial ligation, although these procedures have high complication rates. Stuttering priapism has no evidence-based preventive treatment.

PHIMOSIS

Principles

Phimosis is a constriction of the foreskin that prevents retraction of the prepuce from the glans. Most cases are physiologic, representing normal development, and do not require intervention. Four percent of newborns, 25% of 6-month-olds, 50% of 1-year-olds, 80% of 2-year-olds, and 90% of 4-year-old boys have fully retractable foreskins. Trauma, infections, chemical irritation, poor hygiene, congenital abnormality, or a complication of circumcision may contribute to the development of phimosis.

Clinical Features

The foreskin is not retractable on history, with narrowing or diversion of the urinary stream and foreskin bulging with urination. Phimosis may be accompanied by pain, hematuria, urinary obstruction and, rarely, glans ischemia and infarction.

Management

Gentle retraction and good hygiene are mainstays of management. Retraction of the prepuce should not be forced, because this can lead to future adhesions and strictures. A 6- to 8-week course of topical corticosteroids (eg, 0.1% triamcinolone topical cream), applied to the outlet twice daily, may expedite the development of retractable foreskin. With vascular compromise of the glans, a

CHAPTER 173  Genitourinary and Renal Tract Disorders

Paraphimosis can be caused by infection, masturbation, trauma, hair or clothing tourniquets, or failure to reduce the foreskin after a medical examination or procedure. Paraphimosis is a urologic emergency with potential for arterial compression, penile necrosis, gangrene, and/or autoamputation.

Clinical Features

The history often reveals that the parent or patient retracted the foreskin and then could not replace it over the glans (Fig. 173.3). Physical examination reveals a flaccid proximal penis with erythema and engorgement distal to the obstructing retracted foreskin. The health care provider should verify that the patient is uncircumcised, because hair tourniquet syndrome may mimic paraphimosis.

Fig. 173.2.  Penile analgesia.  (From Davis JE, Silverman MA: Urologic procedures. In Roberts JR, Custalow CB, editors: Roberts and Hedges’ clinical procedures in emergency medicine, Philadelphia, 2014, Elsevier Saunders, pp 1113–1154.)

dorsal split procedure, circumcision, preputial plasty, or balloon dilation may be necessary. Obstructive uropathy can occur secondary to severe stenosis.

Disposition

Patients who are able to urinate and have no evidence of infection or ischemia can be discharged from the emergency department (ED) with outpatient urologic follow-up.

PARAPHIMOSIS

Principles

Paraphimosis is a pathologic condition in which the proximal foreskin cannot be returned to its anatomic position covering the glans penis, resulting in distal venous congestion. Paraphimosis can be caused by infection, masturbation, trauma, hair or clothing tourniquets, or failure to reduce the foreskin after a medical examination or procedure. Paraphimosis is a urologic emergency with potential for arterial compression, penile necrosis, gangrene, and/or autoamputation.

REGIONAL ANESTHESIA OF THE PENIS

A. Dorsal Nerve Block

1. The penis has two dorsal penile arteries and two nerves running together and one dorsal penile vein in the midline. A dorsal nerve block at the base of the penis will provide anesthesia of only the dorsum of the penis.

B. Ring Block

Alternatively, infiltrate subcutaneous lidocaine (without epinephrine) in a circumferential fashion for a ring field block at the base of the penis. This technique provides anesthesia to the entire distal end of the penis.
are applied to crush the foreskin at the 12 o’clock position perpendicular to the corona. After 2 minutes, the prepuce between the hemostats is sharply incised, releasing the constricting band of tissue. The incisions are approximated with 4-0 absorbable sutures. Circumcision should be performed at a later date.

Disposition

Patients can be discharged home with urologic follow-up after reduction if they are able to void spontaneously. Any evidence of cellulitis or necrosis warrants hospital admission, intravenous (IV) antibiotics, and urologic consultation.

**BALANOPPOSTHITIS**

**Principles**

Balanoposthitis, an inflammation that involves the glans and foreskin, occurs in approximately 5% of uncircumcised males.\(^8\) Balanitis involves the glans penis only. Balanoposthitis is usually secondary to poor hygiene, infection (bacterial and fungal), contact dermatitis, chemical irritation, or local trauma. Less commonly, a drug eruption, scabies infection, sexually transmitted infection (STI; eg, human papillomavirus [HPV], herpes), or nummular eczema may cause inflammation. Infectious organisms are gram-negative and gram-positive, including group A beta-hemolytic streptococci and, rarely, Neisseria gonorrhoeae and Chlamydia.

**Clinical Features**

Physical examination reveals penile erythema, edema, and occasionally discharge (Fig. 173.5). Streptococcal balanoposthitis is characterized by a fiery red surface and moist exudate under the prepuce. The patient may have a concomitant or recent streptococcal infection in other locations. Candidal balanoposthitis is associated with generalized erythema, fissuring, eroded papules, and a whitish discharge. Characteristic satellite lesions may be present.

**Management**

Providers should emphasize adequate hygiene with sitz baths to reduce inflammation. Irritants should be avoided. Painful micturition can be addressed by having the child urinate while in a warm water bath. Antibiotic ointments should be used for bacterial superinfection (eg, Polysporin [bacitracin and polymyxin B],
hemorrhage. Significant bleeding may indicate a blood dyscrasia. Local, systemic, or urinary tract infection also can occur.

Management

Postoperative pain usually resolves within 12 to 24 hours. Occlusive dressings can contribute to urinary retention and edema and should be removed. Children may develop urethral meatal stenosis from adhesions of the healing glans. Pain with urination, bloody discharge resulting from an inflamed meatus, high-velocity stream, and the need to sit while voiding indicate adhesions. Postcircumcision phimosis may result if excess foreskin remains, requiring surgical revision.

PENILE ENTRAPMENT AND TOURNIQUET INJURIES

Penile rings, string, wire, and human hair tourniquets can result in penile venous and arterial occlusion.\(^9\) The patient presents with swelling of the glans, wherein the offending agent may be difficult to visualize because of edema of the coronal sulcus. The neurovascular supply can be occluded. Hair tourniquets may be removed with a depilatory agent. The foreign body can be cut with surgical scissors or removed with the string technique (Fig. 173.6). Metal bacitracin, mupirocin). Topical corticosteroids (eg, hydrocortisone, 0.5%–1%) may help inflammation due to contact irritation. Candidal infections should be treated topically with antifungals (eg, clotrimazole, miconazole, nystatin). A blood glucose test should be considered in patients presenting with recurrent candidal balanoposthitis.

Disposition

Systemic antibiotics are indicated in severe infections or when an STI is suspected. Circumcision is recommended for recurrent disease.

COMPLICATIONS OF CIRCUMCISION

Principles

Circumcision prevents phimosis, paraphimosis, recurrent balanoposthitis, and decreases urinary tract infections, sexually transmitted disease transmission (including human immunodeficiency virus [HIV]), and penile cancer. An American Academy of Pediatrics task force has concluded that the benefits of circumcision outweigh the risks.\(^8\) The most common complication is minor hemorrhage. Significant bleeding may indicate a blood dyscrasia. Local, systemic, or urinary tract infection also can occur.

bands may require ring cutters or a saw—cooling of ring will be required during the procedure to avoid penile burns. Providers should document that patients can void once the constriction is relieved. Urethral obstruction can be evaluated with retrograde urethrography. Urologic consultation should be obtained emergently if penile arterial flow is disrupted, the constricting object cannot be removed rapidly, or there are signs of necrosis.

Zipper entrapment of the foreskin typically occurs in children between 2 and 6 years of age. Local anesthesia or sedation may facilitate removal. The zipper can be removed with bone or metal cutters or a mini-hacksaw to cut the median bar of the zipper (Fig. 173.7). The foreskin is freed once the zipper falls apart. Application of mineral oil to the penis may ease zipper removal. Additional methods to release the foreskin under the zipper mechanism include cutting the zipper below the entrapment and pulling the two halves of the zipper apart, cutting the zipper teeth above and below the entrapment and, with pliers, squeezing the median bar to allow more room to disengage the trapped prepuce, and insertion of a flat screwdriver between the face plates of the zipper mechanism to pry open the face plates and allow the prepuce to be released.13

**EPIDIDYMIS**

**Principles**

Epididymitis is inflammation of the epididymis. Infectious causes vary by age. Young children commonly have viral infections. Bacterial epididymitis in prepubertal boys is associated with structural anomalies of the urinary tract. *N. gonorrhoeae* and *Chlamydia trachomatis* are common causes in adolescents. Risk factors include heavy physical exertion, direct trauma, and sexual activity.

**Clinical Features**

Patients present with a painful edematous scrotum and tenderness at the epididymis (Fig. 173.8). A urethral discharge may be present, particularly when the condition is secondary to an STI. Nausea, vomiting, fever, and lower abdominal, scrotal, or testicular pain may be present. Infants and young children may present with isolated fever. As the edema increases, obliteration of the sulcus between the testis and epididymis occurs, making differentiation from testicular torsion difficult. Relief of pain with scrotal elevation (Prehn's sign) is unreliable and should not be used to make the diagnosis.11

**Diagnostic Considerations**

**Diagnostic Testing**

Urine analysis and urine culture should be part of the ED evaluation for all infants and children younger than 2 years. In children older than 2 years, urine culture should be performed only if the urinalysis results indicate urinary tract infection. Lack of pyuria does not rule out epididymitis; up to 50% of patients have normal urinalysis. Direct urethral evaluation for *N. gonorrhoeae* and *C. trachomatis* is unnecessary because urine specimens are as sensitive with improved rapid nuclear acid amplification testing. Ultrasonography may be indicated in undifferentiated cases to exclude torsion. Increased vascular flow toward the side of the inflamed epididymis may be seen.

**Management**

Scrotal elevation, ice packs to the scrotal area, and pain medications are useful to control pain and inflammation. If urethral discharge is present, sexually active adolescents should be treated presumptively for both *N. gonorrhoeae* and *C. trachomatis*. Ceftriaxone (250 mg intramuscularly) and doxycycline (100 mg bid for 10 days) is preferred treatment. To increase compliance, azithromycin (1 g once) may be used instead of doxycycline, although there are little data on the use of azithromycin for chlamydial epididymitis. Follow-up for resolution of symptoms should occur if azithromycin used. In children, non-sexually acquired epididymitis without evidence of a urinary tract infection may be managed expectantly without antibiotics.12 Infants with or without positive findings on urinalysis and young children with positive urinalysis findings may be treated with cephalaxin tid if a bacterial urinary tract infection is suspected. *Mycoplasma genitalium* and *Ureaplasma urealyticum* may cause chronic epididymitis, and erythromycin, clarithromycin, or azithromycin may be used if symptoms persist.

**Disposition**

Patients with systemic symptoms and toxicity should be admitted for IV antibiotic therapy with ceftriaxone or cefotaxime. Follow-up with the pediatrician or urologist is needed to evaluate for contributing anatomic abnormalities and ensure symptom resolution.
ORCHITIS

Principles
Orchitis is a result of a bacterial or viral testicular infection leading to diffuse edema, pain, and discoloration of the scrotum. Paramyxovirus is most common, associated with mumps. Other causes include Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Staphylococcus or Streptococcus spp., Epstein-Barr virus, coxsackievirus, arbovirus, enterovirus, Brucella, granulomatous disease, and filariae.\(^{13}\)

Clinical Features
During the course of mumps, orchitis usually develops after the first week and is manifested with tenderness and edema of the testis, with discoloration of the scrotum. Bilateral cases are relatively rare, occurring in 2% to 5% of affected patients. If epididymitis coexists, a urethral discharge may be present. Bacterial orchitis can result in scrotal abscess formation.

Diagnostic Considerations
Diagnostic Testing
Doppler ultrasound imaging may be necessary to distinguish orchitis from testicular torsion.

Management and Disposition
Treatment of viral orchitis is aimed at pain control (scrotal elevation, nonsteroidal anti-inflammatory drugs [NSAIDs], and possibly narcotics). When the diagnosis is unclear or when concurrent epididymitis is suspected, treat with oral antibiotics covering gram-negative bacteria (eg, a third-generation cephalosporin). A urologist should be urgently consulted for a scrotal or testicular abscess. Most cases can be managed on an outpatient basis.

TESTICULAR TORSION

Principles
Testicular torsion is the most concerning cause of an acutely painful scrotum. Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, necrotic gangrenous testes. Testicular salvage rates are time-dependent. Nearly 100% of testes can be saved if detorsed within 4 hours of symptom onset. This decreases to less than 10% if there is more than a 24-hour delay to treatment. Testicular torsion can occur at any age. A small incidence peak occurs in the neonatal period but most cases occur in those from 12 to 18 years of age.\(^{14}\)

Typically, the tunica vaginalis attaches to the posterior wall of the hemiscrotum and superior pole of the testis to achieve testicular fixation. If the tunica completely covers the testis and attaches higher up on the spermatic cord (bell clapper deformity), proper testicular fixation does not occur, and there is a predisposition to torsion (Fig. 173.9). In intravaginal torsion, the testicle may rotate within the tunica vaginalis, thereby constricting the arterial blood flow. Extravaginal torsion can occur antenatally and is most common in premature neonates.

Clinical Features
Patients present with acute scrotal pain and swelling, an elevated testicle and, typically, absence of the cremasteric reflex. This reflex can be demonstrated by lightly stroking the skin of the inner thigh.

downward from the hip toward the knee. The cremaster muscle on the ipsilateral side rapidly contracts and elevates the testicle. Although absent in the vast majority of cases, the presence of the cremasteric reflex does not preclude testicular torsion.11,14,15 Abnormal (high-riding and transverse) epididymal and testicular position may also be noted, with left-sided torsions slightly more common than right. Pain is typically constant, and the patient may have a history of a similar prior episode. Up to 90% of patients have associated nausea and vomiting. Cryptorchism (one or both testes are undescended) increases the risk of torsion and may present with abdominal or inguinal pain.14,15,17 Familial history and recent trauma may increase the risk of torsion.14 Because adolescent males may be embarrassed to report testicular or scrotal pain, all males with abdominal pain should have their testes examined.

**Diagnostic Considerations**

**Diagnostic Testing**

Emergent urologic consultation should be obtained for patients with suspected testicular torsion. In undifferentiated cases, Doppler ultrasonography is indicated.11,12 Ultrasonic sensitivity is 85% to 98% (although operator-dependent), with specificity close to 100%. Scintigraphy and magnetic resonance imaging (MRI) are less commonly used imaging options, but may be considered for indeterminate ultrasound results. Homogeneous echotexture on ultrasound is predictive of testicular viability and justifies emergent surgical exploration. Heterogeneous parenchymal echotexture indicates testicular nonviability in the setting of prolonged symptoms.

**Management**

Immediate surgical exploration is indicated with clinical suspicion of torsion (particularly within 12 hours of symptom onset) and should not be delayed for diagnostic studies. Detorsion of the affected testicle is surgically performed, followed by an elective orchiopexy of the contralateral side to avoid recurrence. Approximately 40% of patients have a bell clapper deformity of the contralateral testicle. Bedside manual detorsion may be performed with analgesia if operative repair is delayed. The testicle is rotated in an open book fashion as viewed from below, from medial to lateral, until detorsion is complete. Torsion may cause ischemia at 180 degrees of rotation but typically occurs with 360 degrees of twisting. Up to one-third of patients may torsse laterally; in these cases, manual reduction worsens torsion and its symptoms, and the procedure should be halted. After a successful detorsion, a postprocedure testicular compartment syndrome may occur secondary to testicular edema within the tight tunica albuginea. Elective (rather than emergent) orchiectomy with contralateral orchiopexy may be indicated for a patient with prolonged symptoms and an ultrasound consistent with testicular nonviability. Caution must be exercised in these cases because intermittent torsion can occur. This decision should be made by discussion with the consulting urologist and emergency clinician.

Both the appendix of the testis and appendix of the epididymis can torsse, although the former is much more common. Patients with appendicular torsion present with moderate pain of sudden onset localized to the involved hemiscrotum. The pathognomonic blue dot sign (<3 mm bluish hue in the upper lateral hemiscrotum—a cyanotic appendage) is present in less than 25% of cases.15 Color Doppler ultrasound should be performed when the diagnosis is uncertain and will reveal normal or increased flow to the affected testicle.15 Conservative therapy with analgesics and scrotal support is indicated; the involved appendix undergoes autoamputation within 1 week, accompanied by resolution of symptoms.11,18

**VARICOCELE**

A varicocele is a collection of venous varicosities of the spermatic veins in the scrotum caused by incomplete drainage of the pampiniform plexus. Varicoceles occur in 10% to 20% of males but are rare in children younger than 10 years. Most are left-sided.

The diluted venous collection may be tender on physical examination. It can be palpated superiorly and posteriorly to the testes. Patients should be examined in the supine and upright positions; varicoceles are more pronounced when upright. Varicoceles are described as a “bag of worms” in appearance and on palpation. Patients with varicoceles that are sudden in onset, right-sided, or do not diminish in the supine position should undergo imaging (eg, ultrasonography, computed tomography [CT], or MRI) to evaluate for a retroperitoneal neoplasm. Surgical correction may be required if the patient becomes symptomatic or has bilateral varicoceles.

**IDIOPATHIC SCROTAL EDEMA**

Idiopathic scrotal edema is erythema and induration of the scrotum that is typically painless but may be pruritic. There is no clear cause.19 Most cases are unilateral and usually occur in prepubertal boys 5 to 11 years of age. There is minimal tenderness on physical examination, but the edema and erythema may extend to the phallus, groin, and abdomen. Examination of the testes and epididymis reveals no palpable masses. Systemic signs and symptoms are rare. Ultrasonography typically demonstrates thickening of the scrotal wall and increased peritesticular blood flow.19 Patients can be discharged home with outpatient follow-up after an acute pathologic process has been ruled out. Most cases resolve spontaneously within a few days. NSAIDs and scrotal support may alleviate symptoms. Recurrences are typically more severe and occur in up to 21% of patients.19

**HYDROCELE**

A hydrocele is a collection of fluid that accumulates in the tunica albuginea. Communicating hydroceles have an open tract between the peritoneum and scrotum. The tract is closed in noncommunicating hydroceles. Most hydroceles are right-sided. Hydroceles are common in newborns and most resolve spontaneously within 1 year. Hydroceles persistent beyond 1 year of age will often require surgical repair. In older children and adolescents, they may occur secondary to epididymitis, orchitis, testicular torsion, appendix testis or epididymis torsion, trauma, or tumor.

Examination with transillumination reveals enlargement of the scrotum. Color flow Doppler ultrasonography may be necessary to determine the cause of the hydrocele and exclude an acute pathologic process in patients with acute symptoms of pain. Asymptomatic patients can be discharged home with urologic follow-up for further evaluation and management.

**INGUINAL HERNIA**

**Principles**

Inguinal (direct and indirect) hernias are more common in males, with bimodal peaks before 1 year of age and after the age of 40 years. Infants are anatomically at risk for an inguinal hernia secondary to a short inguinal canal that crosses the abdominal wall perpendicularly, as opposed to obliquely in adults. Premature birth doubles the risk of inguinal hernia, likely in association with conditions that increase intra-abdominal pressure, such as mechanical ventilation. Infants often present with incarceration. Although hernias are more common in infant males, incarceration is more common in girls. Additionally, girls are more likely
to have an incarcerated ovary rather than bowel. Concomitant ovarian torsion may occur with inguinal hernias and should be suspected with continued irritability after successful hernia reduction. Patients should receive a urgent surgical referral because reduced incarcerated hernias commonly recur within days. See Chapter 89 for a further discussion of inguinal hernias.

**TESTICULAR CARCINOMA**

**Principles**

Testicular and scrotal cancers represent approximately 1% of solid tumors in children. Testicular cancer is one of the most curable solid tumors, particularly when diagnosed early. Cryptorchism increases the risk of testicular cancer in the undescended testicle and contralateral descended testicle. Tumor types include teratomas, embryonal carcinomas, yolk sac tumors, choriocarcinomas, Leydig cell tumors, and Sertoli cell tumors. Lymphoma and leukemia can also metastasize to the testicle.

**Clinical Features**

Patients typically present with a painless unilateral mass palpated separately from the testis or may describe a feeling of fullness, tugging, or increased weight of the scrotum and testicular enlargement. A reactive hydrocele may be present in 7% to 25% of patients and may contribute to diagnostic delay. The physical examination reveals a firm mass, smooth or nodular, that cannot be transilluminated. A complete physical examination looking for lymphadenopathy, petechiae, abdominal mass, hepatosplenomegaly, or gynecomastia should be performed. Diagnostic evaluation includes a CBC, urinalysis, urine human chorionic gonadotropin (produced by germ cell tumors) assay, and ultrasonography of the testis.

**URINARY TRACT INFECTIONS**

**Principles**

A urinary tract infection (UTI) is a common cause of fever in young children. Neonatal boys are more susceptible than girls but, beyond that, females are at higher risk. Vesicoureteral reflux from the bladder into the ureter is a common cause of recurrent urinary infections, including pyelonephritis. Resultant renal scarring may increase the risk of hypertension or lead to renal failure later in life.

The baseline incidence of asymptomatic bacteriuria in young children is 1%. The diagnosis of a UTI in children requires urinalysis results suggesting infection (pyuria, bacteriuria, or both) and the presence of at least 50,000 colony-forming units (CFU) per milliliter of a uropathogen cultured from a urine specimen. *E. coli* is the predominant cause of UTIs in children; *Klebsiella* species are more likely in newborns. Other pathogens include *Enterobacter, Proteus, Morganella, Serratia*, and *Salmonella* spp. *Lactobacillus*, coagulase-negative *Staphylococcus*, and *Corynebacterium* are not considered clinically relevant pathogens in otherwise healthy children. UTIs in infants younger than 3 months are associated with bacteremia in up to 50% of cases and 5% in older children.

**Clinical Features**

Approximately 5% of children younger than 2 years with a temperature above 39°C (102.2°F) and without a source for the fever have an occult UTI; approximately 75% of children younger than 5 years with a febrile UTI have pyelonephritis. Girls younger than 2 years and uncircumcised boys younger than 12 months are at higher risk for UTI. Fever duration correlates with the prevalence of UTIs, with 2 days of fever more likely than 1 day of fever to be associated with a UTI.

UTIs in children younger than 2 years often present with nonspecific symptoms, such as decreased oral intake, lethargy, jaundice, fever, vomiting, abdominal pain, and irritability. Children older than 2 years may have local symptoms of cystitis such as suprapubic tenderness or dysuria. Systemic symptoms of pyelonephritis include fever, costovertebral angle tenderness, abdominal pain, vomiting, and ill appearance. New-onset bedwetting also may be a sign of a UTI.

**Diagnostic Considerations**

**Diagnostic Testing**

Sterile urethral catheterization is the preferred method of urine collection. In infants, chances of a full bladder improve if 45 to 60 minutes have elapsed since the last diaper change; ultrasound enhances the probability of obtaining urine. Bagged urines have false-positive rates of 12% to 83% due to contamination by periurethral flora and should not be used. Because urethral catheterization is almost always successful, suprapubic aspiration is rarely needed.

Nitrite and leukocyte esterase markers have the highest combined sensitivity and specificity; the false-positive rate is less than 4% when both are positive. A Gram stain of the urine increases the sensitivity to 93%, but has not been shown to change ED management. In children younger than 2 years, urinalysis alone is not adequate to rule out a UTI. The nitrite test measures conversion of nitrates to nitrites by gram-negative bacteria, but this may not occur in young infants who urinate frequently. Leukocyte esterase requires the presence of leukocytes. Sensitivities of both tests remain low enough that urine cultures should be ordered on children younger than 2 years old. Renal function test results are rarely abnormal but should be obtained in children with hypertension, proteinuria, or signs of dehydration. Blood cultures are not indicated in well-appearing children because the true-positive rate is low, and the organism identified is invariably the urinary pathogen.

**Differential Diagnoses**

Underlying renal disease or urinary tract abnormally should be considered in children presenting with hypertension, hematuria, elevated blood urea nitrogen (BUN) or creatinine level, electrolyte abnormalities, or acidosis.

Diabetes may present with urinary frequency, mimicking a UTI. Other causes of dysuria in children include irritants such as bubble bath or soaps, retained vaginal foreign bodies, and pinworms (Box 173.1). The possibility of sexual abuse should be considered in any child with a history of multiple UTIs without a cause, such as vesicoureteral reflux.

**Management**

**Younger Than 2 Months**

Infants younger than 2 months are more at risk for sepsis. It was formerly recommended that young infants receive a full sepsis evaluation and admission to the hospital for IV antibiotic therapy (eg, with gentamicin or cefotaxime and ampicillin). However, studies have shown it may be safe to treat a subset of young infants (29-60 days of age) with UTIs on an out-patient basis if they appear well in the ED and have good follow-up.
HEMATURIA

Principles

Red blood cells (RBCs) can enter the urinary tract from inflammation, infection, trauma, or anatomic abnormalities, anywhere from the glomerulus to the urethra. Microscopic hematuria is defined as more than 5 RBCs/mm³; macroscopic or gross hematuria is the presence of blood or clots visible to the naked eye. The causes of hematuria can range from simpler factors, such as exercise or a UTI, to more serious factors, such as glomerular disease.

Clinical Features

The history and physical examination (including genital examination) should focus on signs of infection, trauma, or bleeding disorders. Providers should look for signs of renal disease (eg, glomerulonephritis), including hypertension, facial edema, rales, and cardiac murmurs.

Diagnostic Considerations

Differential Diagnoses

The causes of hematuria can be divided into extrarenal, intrarenal, and systemic illnesses (Box 173.2). Urine with lysed RBCs or myoglobin from muscle breakdown tests positive for hemoglobin, yet will not contain RBCs. Certain drugs or foods, such as phenothiazines, ibuprofen, beets, and blueberries, can cause reddish urine. In neonates, urate crystals can cause a benign red-tinged urine in the diaper, also termed brick dust urine.

BOX 173.2

Cause of Hematuria in Children

EXTRARENAL
Trauma
Meatal stenosis or posterior urethral valves
Exercise
Menstruation or rectal bleeding
Foreign bodies
Cystitis, urethritis, or epididymitis

INTRARENAL
Pyelonephritis
Renal or bladder stones or tumors
Poststreptococcal or idiopathic glomerulonephritis
Acute interstitial nephritis
Acute tubular necrosis
Basement membrane glomerular disease
Renal vein or artery thrombosis
Recurrent familial hematuria
Polycystic kidney disease

SYSTEMIC
Alport syndrome nephritis
Henoch-Schönlein purpura
Systemic lupus erythematosus
Hemolytic-uremic syndrome
Infectious mononucleosis
Sickle cell disease or other hemoglobinopathies
Bacterial endocarditis or artificial cardiac valves
Bleeding disorders, warfarin, or aspirin
Medications such as amitriptyline or chlorpromazine, radiocontrast dyes
Munchausen syndrome or factitious

2 Months to 2 Years

Well-appearing children, 2 months to 2 years old, without signs of toxicity may have the UTI managed on an outpatient basis. Oral antibiotic therapy is as effective as initial parenteral therapy; health care providers should be familiar with their local antibiotic resistance patterns, because rates of E. coli resistance to trimethoprim-sulfamethoxazole can be as high as 20% to 30%. Lower rates of resistance for first-generation cephalosporins (eg, cephalexin, amoxicillin-clavulanate), third-generation cephalosporins (eg, cefixime, cefpodoxime, cefdinir, cefotaxime, ceftriaxone), and aminoglycosides (eg, gentamicin) have been reported. Antibiotics that are excreted in the urine but do not reach sufficient levels in the bloodstream, such as nitrofurantoin, should not be used.

Because UTIs in this age group are considered to be upper tract disease processes, a 7- to 14-day course of antimicrobials is indicated. Patients should be followed clinically over the first 3 days of treatment until culture results provide antibiotic sensitivities. Follow-up imaging such as renal and bladder ultrasound looking for evidence of anatomic abnormalities or renal scarring may be completed on an outpatient basis.

Older Than 2 Years

Children older than 2 years with simple cystitis should be treated with a short 3-day course of antibiotics, such as cephalexin or amoxicillin-clavulanate. Courses shorter than 3 days result in higher failure rates and are not recommended. Older children with pyelonephritis should receive a 7- to 14-day course of antibiotics. Fluoroquinolones are not recommended for children due to possible musculoskeletal toxicity.

Disposition

Children with signs of toxicity, urinary obstruction, or inability to take oral medications should be hospitalized to receive IV antibiotics. The discharged patient should receive instructions to return if he or she is not able to take orals or symptoms worsen. Even with appropriate treatment, children with UTIs may remain with lower grade fevers for 48 hours, despite clinically improving.
Diagnostic Testing

A urinalysis with more than 5 RBCs per high-power field or gross blood indicates hematuria. The presence of white blood cells (WBCs) or leukocyte esterase indicates infection. Associated RBC casts, large proteinuria, hypertension, or renal insufficiency may indicate glomerular pathology. With hematuria, the urine dipstick may be positive for protein, but should not exceed 2+ (100 mg/dL) if hematuria is the only cause of the proteinuria. If glomerular disease is suspected, especially in the setting of a recent pharyngeal or skin infection, a throat culture, antibody test for Streptococcus, and complement studies should be ordered. Complement levels are lowered in poststreptococcal glomerulonephritis. If the patient has signs of hypertension, edema, weight gain, or proteinuria, nephrotic syndrome should be considered, and laboratory tests for electrolytes, total protein, and albumin should be ordered. The erythrocyte sedimentation rate and antinuclear antibody assay are indicated if diseases such as systemic lupus erythematosus are possible. Hypercalciuria is a common cause of microscopic and gross hematuria; urine and plasma calcium levels should be measured if no other cause of the hematuria is found. It has been theorized that microcalculi produced by the hypercalciuria cause irritation of the uroepithelium.

Management

Disposition will depend on the underlying cause for the hematuria. Well-appearing children with no identifiable cause of hematuria should follow up with a primary care provider for a 24-hour urine collection to measure creatinine and protein levels.

RENAL STONES

Principles

Renal stones in children have been increasing in incidence. Calcium-containing stones are responsible for approximately 60% of all cases, followed by struvite, uric acid, and cystine stones. Congenital abnormalities, trauma, or infection also can be an inciting cause. Renal stones are three to four times more common in white children, and a family history increases the risk. In younger children, renal stones predominate over ureteral stones.

Clinical Features

Older children typically have colicky flank pain, vomiting, and hematuria. Younger children with renal stones can present with less specific complaints, such as nontender abdominal pain, vomiting, or malaise, and sometimes only isolated hematuria. History should include prior UTIs (Proteus species may potentiate struvite stones), family history of renal stones, and diet (including excessive vitamin use) and fluid intake. Toxins have also been associated with the development of renal stones.

Diagnostic Considerations

Diagnostic Strategies

Urine should be checked for hematuria and evidence of infection, such as positive leukocyte esterase or nitrates, leukocytes, and bacteria. CBC, electrolyte panel, BUN and creatinine levels, and urine culture should be ordered, especially for the first episode of renal stones. Additional laboratory testing such as calcium or uric acid levels can be ordered during follow-up with a pediatric urologist.

Non–contrast-enhanced helical CT has high sensitivity and specificity for the detection of calculi as small as 1 mm and can identify associated processes, such as obstruction, hydroureret, hydrocalyx, and renal abscess. Ultrasonography is often an alternative first choice in young patients to avoid radiation because renal stones predominate over ureteral stones in this population. Sensitivity of ultrasonography with experienced ultrasonographers is up to 90% for renal stones but much lower for ureteral stones. If the results of the ultrasound are equivocal, CT imaging should be considered, especially for presumed first-time renal stones.

Differential Diagnoses

Gastroenteritis and constipation are more common causes of colicky abdominal pain in young children. Intermittent abdominal pain associated with intussusception usually occurs in children younger than 2 years. In adolescents, biliary colic and intermittent gonadal torsion should also be considered.

Management

Management of pediatric nephrolithiasis is similar to that for adults (see Chapter 89). Children with normal renal function and adequate pain control, without signs of toxicity or renal infection, can be safely discharged home, with good follow-up. Stones 5 mm or smaller appear to pass safely in pediatric patients.

RENAL TUMORS

Principles

Renal tumors in children range from the benign cystic nephroma to the more aggressive malignant rhabdoid tumor. Most abdominal masses in infants are benign renal tumors or cysts.

Clinical Features

The most frequent presentation for a child with a renal tumor is that of an abdominal mass found by the parent while bathing or dressing the child. Hematuria or pain is a less common presenting manifestation than in the adult population.

Diagnostic Considerations

Diagnostic Testing

Because most abdominal masses are renal cysts, renal ultrasonography, which exposes the child to no radiation, is the initial imaging study of choice. Laboratory tests should include CBC, platelet count, BUN and serum creatinine levels, urinalysis, and urine catecholamine levels, which are increased in 95% of patients with neuroblastoma but normal in those with Wilms’ tumor. Once a solid mass is found on ultrasonography, CT should be performed to define the mass better. If the mass appears malignant on the CT scan, additional imaging (eg, CT brain or positron emission tomography [PET] scan) will identify metastases.

Differential Diagnoses

Differential diagnosis for a renal mass includes cystic lesions, such as those of polycystic kidney disease, and severe hydronephrosis resulting from obstruction or severe reflux. Solid masses include Wilms’ tumor, neuroblastoma, renal cell carcinoma, mesoblastic nephromas, and cystic nephromas.

Disposition

A preliminary diagnosis of the cause of the mass should be obtained before discharge of the child from the ED. Well-appearing
children with normal renal function for whom close follow-up can be ensured may be managed on an outpatient basis. A preliminary diagnosis of a renal tumor may require admission for coordination of continued evaluation and final diagnosis.

PROTEINURIA

Principles

Trace to mild proteinuria (1+ to 2+) is a common laboratory finding in young children and can represent benign conditions, such as exercise or mild dehydration, or more serious causes, such as nephrotic syndrome. Albumin, a high-molecular-weight protein, does not pass through the glomeruli into the urine; low-molecular-weight proteins, however, do pass through the glomeruli and are reabsorbed in the proximal tubule. Proteinuria can result from increased passage of protein molecules such as albumin through the glomeruli or decreased reabsorption by the tubules. In most cases, proteinuria is benign and asymptomatic. If the amount of protein lost is significant, such as in nephrotic syndrome, the resultant hypoalbuminemia (albumin level through the glomeruli or decreased reabsorption by the tubules. Proteinuria can result from increased passage of protein molecules such as albumin through the glomeruli or decreased reabsorption by the tubules. In most cases, proteinuria is benign and asymptomatic. If the amount of protein lost is significant, such as in nephrotic syndrome, the resultant hypoalbuminemia (albumin level < 2 g/dL; protein level < 4 g/dL) may cause ascites and generalized edema.

Clinical Features

The presenting symptoms in children depend on the cause of the proteinuria. Patients may have hypertension, edema (often facial), ascites or, in infants, palpable kidneys. Recent pharyngitis or the presence of hematuria may indicate an inflammatory renal process such as poststreptococcal glomerulonephritis. Changes in weight, urine output, or family history of proteinuria may indicate nephrotic syndrome. A butterfly rash of systemic lupus or the purpuric rash of Henoch-Schönlein purpura may also indicate the underlying cause of proteinuria.

Diagnostic Considerations

Differential Diagnoses

Causes of proteinuria can be glomerular or tubular. Glomerular causes include nephrotic syndrome, glomerulonephritis, and posttransplantation rejection. Transient causes of altered glomerular function include exercise, extreme cold or heat, fever, seizures, and stress. Tubular causes of proteinuria include heavy metal poisoning, urinary tract infections, and diabetes, as well as an asymptomatic tubular proteinuria. Urinary dipstick testing can lead to a false-positive result for proteinuria when the urine is alkaline or contains mucus, blood, vaginal secretions, semen, or a significant number of inflammatory cells. In addition, dilute urine (specific gravity < 1.010) can lead to a false-negative result.

Orthostatic proteinuria is a benign condition characterized by protein in the urine collected with the patient in an upright position but not in samples collected from a supine child. Proteinuria that is persistent or associated with hematuria or other signs of renal disease such as an elevated BUN or creatinine level usually is a sign of a more serious condition.

Diagnostic Testing

Mild proteinuria (1+; equivalent to ≤100 mg/dL) requires no further investigation. Evidence of a UTI, such as WBCs or a positive leukocyte esterase or nitrite level, should be treated. Patients with moderate proteinuria (2+; equivalent to ≤300 mg/dL) should have additional testing, including the total serum protein, albumin, electrolyte, BUN, and creatinine levels, and urine culture. A random urine protein-to-creatinine ratio (urine Pr/Cr, expressed in mg/dL) correlates strongly with the protein levels found in a 24-hour urine collection. The normal urine Pr/Cr value in children older than 2 years and adults is less than 0.2 mg/dL; the normal value for children 6 months to 2 years of age is less than 0.5 mg/dL. A urine Pr/Cr more than 3.0 mg/dL correlates to nephrotic syndrome. Children with elevated urine Pr/Cr levels should be referred to a nephrologist for a 24-hour urine collection for protein.

An antistreptolysin O (ASO) titer can identify a previous streptococcal infection as the cause of the proteinuria. In young children, renal ultrasonography detects polycystic disease or anatomic abnormalities, but may be deferred as an outpatient study if the patient is being discharged. Children with proteinuria should be referred to their primary care physician, or a follow-up with a pediatric nephrologist is indicated. Indications for renal biopsy may include increased creatinine levels, low complement levels, and hematuria.

Disposition

A child with significant edema and ascites, significant hypertension (>99th percentile for age and height) resulting from glomerulonephritis, or marked impairment of renal function (>50% over normal) should be hospitalized. Consultation with a pediatric nephrologist may be beneficial in deciding whether to discharge a child home. Well-appearing children can be discharged home, with close follow-up.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Principles

Poststreptococcal glomerulonephritis (PSGN) is one of the most common glomerulonephritides. PSGN is a sequelae of streptococcal pharyngitis and, less commonly, streptococcal skin infections. PSGN is believed to result from the deposition of circulating immune complexes in the kidney. How those immune complexes develop is not completely understood. These immune complexes result in decreased glomerular filtration, allowing proteins to flow freely into the urine.

Although PSGN remains more of a cause of morbidity and mortality in developing countries, its overall incidence has been declining in industrialized countries. Antibiotics for streptococcal pharyngitis have not been definitively shown to prevent PSGN. However, there is some evidence that prophylactic treatment of at-risk individuals in developing countries can curtail epidemics.

Clinical Features

PSGN usually occurs in children 3 to 7 years of age, usually with a history of pharyngitis, with fever 2 weeks before the onset of glomerulonephritis (or up to 6 weeks after skin infections). Symptoms can be localized to the urinary tract, manifested as hematuria or flank pain, or may be less specific, with lethargy or generalized edema. Some children may present with pulmonary edema, cardiac arrhythmias, or hypertension. Renal failure is found in 2% of these patients. Delay in the diagnosis of PSGN may occur with a negative infection history and absence of gross hematuria.

Diagnostic Considerations

Diagnostic Testing

In PSGN, urinalysis will show significant blood and protein, with RBC casts in 60% of cases. Other findings may include pyuria, with granular or hyaline casts. The BUN level will be elevated;
Nephrotic syndromes are kidney diseases that result in significant proteinuria, hypoproteinemia, and edema. Although hypoalbuminemia defines the diagnosis of nephrotic syndrome, levels of other important proteins such as immunoglobulins can also be reduced by the disease. From one to seven cases of nephrotic syndrome/100,000 children are discovered each year; boys are affected twice as often as girls. Primary nephrotic syndromes commonly occur in children younger than 5 years. Of children with nephrotic syndrome, 90% have the primary type, the vast majority due to minimal change nephrotic syndrome. Secondary nephrotic syndrome usually occurs in older children and results from a systemic illness, such as PSGN or lupus nephritis.

Clinical Features

Characteristics of nephrotic syndrome include edema, hypoalbuminemia, proteinuria, and hyperlipidemia. The onset of edema may be insidious, beginning with periocular edema. As weight increases, pants and shoes may not fit. The edema progresses, but the child usually does not appear ill unless she or he has pulmonary edema or ascites. Other features may include anorexia, nausea, and vomiting secondary to edema of the intestine. Hypertension, hematuria, or oliguria may be present. Acute renal failure is rare in primary nephrotic syndrome.

Nephrotic children are at increased risk for thrombosis, with 2% developing thromboembolic complications. Renal veins are particularly vulnerable to thrombosis, leading to flank pain, hematuria, and impaired renal function. Children with nephrotic syndrome who are taking corticosteroids are at greater risk for side effects of the steroids. Health care providers should counsel families on the possibility of acute mood changes, from depression to mania, with steroid use. Steroid therapy and decreased levels of immunoglobulins put nephrotic children at risk for bacterial infections, resulting in Streplococcus pneumoniae peritonitis as well as gram-negative, typically E.coli, infections and staphylococcal cellulitis.

Diagnostic Considerations

Diagnostic Testing

Nephrotic-range proteinuria is a daily excretion of more than 3.5 g of protein/1.73 m² or more than 50 mg/kg, corresponding to 3+ or 4+ on the urine dipstick. The specific gravity may be high, and microscopic hematuria may be present. The total serum protein is usually low, 4.5 to 5.5 g/dL, and the albumin level is usually less than 3 g/dL. A random urine Pr/Cr, expressed in mg/dL, correlates strongly with the protein levels found in a 24-hour urine collection. The normal urine Pr/Cr value in children younger than 2 years and adults is less than 0.2 mg/dL; the normal value for children 6 months to 2 years of age is less than 0.5 mg/dL. A urine Pr/Cr more than 3.0 mg/dL or Pr/Cr correlates to nephrotic syndrome. Children with elevated urine Pr/Cr values should be referred to a nephrologist for a 24-hour urine collection for protein.

Complement levels should be normal. For reasons not completely understood, but triggered by changes in oncotic pressure, patients with nephrotic syndrome can develop hyperlipidemia. Hyponatremia may be present, but other electrolyte levels are usually normal. If an elevated cholesterol level is present, the lowered sodium level may be a combination of true hyponatremia and pseudohyponatremia. BUN and creatinine concentrations are usually normal, and hemoglobin and hematocrit levels may be elevated because of hemoconcentration.

Chest radiographs may show pleural effusions or pulmonary edema. The heart appears normal or small because of hypovolemia. An abdominal radiograph may reveal ascites; ultrasonography is usually nonspecific but may show abnormalities such as enlarged kidneys due to edema or small kidneys due to chronic disease. Renal biopsy facilitates diagnostic and therapeutic decisions and is indicated for patients with evidence of hematuria, elevated BUN level, or persistent hypertension or in whom renal dysfunction fails to respond to steroids.

Differential Diagnoses

Other renal diseases that cause edema include glomerulonephritis and renal failure; signs of these diagnoses would include gross blood or RBC casts in the urine, hypertension, or elevated creatinine level. Gastrointestinal disorders that cause hypoproteinemia include cirrhosis, cystic fibrosis, and protein-losing enteritides.

Management

Despite their edema, children with signs of hypovolemia or shock should be resuscitated with crystalloid. Patients with a
presumptive diagnosis of primary nephrotic syndrome (no gross hematuria or elevated creatine level, normal complement levels, and no evidence of extrarenal causes such as a malar rash) may be treated with corticosteroids. After the initial evaluation is completed, patients should receive prednisone, 2 mg/kg/24 hours orally (PO), divided bid, with continued dosing determined by a pediatric nephrologist. Relapses or steroid resistance may necessitate a second course of steroids. Minimal change disease, the most common form of primary nephrotic syndrome in children, is usually very responsive to steroid treatment. Patients should receive a diuretic (eg, furosemide, 1 to 2 mg/kg/24 hours) PO or IV, for respiratory distress or severe ascites. Salt restriction may be required. Fluid should be restricted if edema is present despite salt restriction or in the setting of hyponatremia. Because they are relatively immunocompromised, nephrotic children with fever should likely be admitted to the hospital, have blood cultures, and receive antibiotic therapy with activity against S. pneumoniae and E. coli. An intercurrent infection, even if viral, can also put the nephrotic child at risk for relapse, so admission may also be advised by the nephrologist. Paracentesis should be performed on children with ascites and peritoneal signs; fluid should be sent for cell and differential counts, Gram staining, and culture.

Disposition

Newly diagnosed children with nephrotic syndrome are often hospitalized to facilitate initial evaluation, treatment, and education of the child and parents. Patients with signs of shock or respiratory distress should be admitted to the hospital after initial stabilization. Other patients with suspected bacterial infection, peritonitis, edema refractory to therapy, or evidence of renal insufficiency should also be hospitalized.

**ACUTE KIDNEY INJURY**

**Principles**

Acute kidney injury, previously known as acute renal failure, results from impaired glomerular filtration rate and may affect blood pressure, acid-base balance, removal of nitrogen waste, and fluid management. Acute kidney injury can be divided into three categories—prerenal, which involves decreased renal perfusion; renal (intrarenal), caused by parenchymal damage; and postrenal, which involves obstruction of the urinary tract (Box 173.3).

**Clinical Features**

Children with acute kidney injury can present with hypertension, edema, decreased urine output, and microscopic or gross hematuria. Other signs or symptoms are related to the underlying cause—for example, heart failure, poststreptococcal glomerulonephritis, or a vasculitis such as Henoch-Schönlein purpura. Acute kidney injury can result in life-threatening complications, including severe hyperkalemia, hyponatremia, pulmonary edema or fluid overload, hypertensive encephalopathy, septic shock from renal obstruction and infection, and seizures from metabolic abnormalities or encephalopathy.

**Diagnostic Considerations**

**Diagnostic Testing**

Preliminary laboratory tests should include CBC, electrolyte, calcium, phosphorus, BUN, and creatinine levels, and urinalysis with microscopy and culture. Additional diagnostic studies may include ASO titer (for acute PSGN), C3 complement (for lupus), total serum albumin, cholesterol level, and albumin-to-globulin ratio and urine Pr/C ratio (for cirrhosis and nephrotic syndrome). RBC casts in the urine indicate glomerulonephritis. WBC casts indicate an infective cause, whereas hyaline casts suggest dehydration or acute tubular necrosis. Ultrasonography is indicated to evaluate obstructive causes of renal failure. Ultrasonography may also reveal small kidneys due to congenital hypoplasia or the parenchymal loss of chronic kidney disease. Voiding cystourethrogram shows extrinsic pressure on the bladder by the posterior urethral valves.

**Differential Diagnoses**

Causes of prerenal injury include hypovolemia (eg, dehydration, burns, hemorrhage), shock (eg, sepsis, anaphylaxis), and congestive heart failure (eg, decreased cardiac output; see Box 173.3). Obstruction of the renal artery or thrombosis of the renal vein can also cause acute kidney injury. Intrarenal causes involve damage to the nephron. Glomerular damage can occur from PSGN (usually), systemic lupus erythematosus, HUS, and sepsis with hypoperfusion. Tubular damage can result from heavy metal poisonings or myoglobin from a crush injury, burn, or hemolytic crisis. Dehydrated children taking NSAIDs can also develop kidney injury. Postrenal injury resulting from an obstruction in the urinary tract may be caused by infection, tumor, renal stones, or posterior urethral valves. Bilateral obstruction of the kidneys can lead to frank renal failure.
Management

Patients with hypovolemia resulting in prerenal acute kidney injury should be rehydrated with a 20-mL/kg bolus of crystalloid to prevent progression to acute tubular necrosis. If no urinary response is obtained after two boluses of crystalloid, there is no evidence of obstruction, and the patient is otherwise euolemic, we recommend diuretics, such as IV furosemide, 1 mg/kg/dose every 2 to 6 hours. Bumetanide may be considered in consultation with a pediatric nephrologist. Mannitol, 0.75 g/kg/dose IV qid, is the third-line option, but is contraindicated with obstruction.

If the child is considered euolemic and has no urine output despite diuretic therapy, renal dose dopamine should be initiated (2–5 µg/kg/minute) in consultation with a pediatric nephrologist. Patients with hypertensive encephalopathy should receive IV blood pressure agents such as nicardipine or labetalol to achieve a controlled 10% to 20% reduction in blood pressure. Further discussion of hypertensive emergencies and treatment can be found in Chapter 74.

Acute kidney injury can lead to seizures secondary to hypertensive encephalopathy or a metabolic derangement. Intractable hyponatremic seizures may necessitate the use of hypertonic saline (3% sodium chloride, 3–5 mL/kg), with each 1 mL/kg increasing the serum sodium level by approximately 1 mEq/L. Once the seizures have ceased, sodium correction should continue more slowly to minimize the risk of central pontine myelinolysis. Correction should occur no faster than 10 to 12 mEq/L in the first 24 hours and no more than 18 mEq/L in the first 48 hours. Hemodialysis or peritoneal dialysis is indicated for symptoms of uremia (protracted vomiting), refractory fluid overload, congestive heart failure with pulmonary edema, electrolyte disturbances (severe hyperkalemia, hyponatremia or hypernatremia), or metabolic acidosis.42

Disposition

All children with acute renal failure should be admitted to the hospital. Any child with signs of congestive heart failure, pulmonary edema, significant hyperkalemia, or acidosis should be admitted to a monitored bed and receive emergent dialysis.

Hypertension

Principles

Hypertension is defined as a systolic or diastolic blood pressure higher than 2 standard deviations (SDs) above the mean for age and gender (Table 173.2). Blood pressure readings should be taken on more than one occasion with appropriately sized cuffs. A child who is in pain or agitated may have falsely elevated blood pressure readings.

Hypertension is seen in boys and girls, occurring more often in African American children. Predisposing factors include obesity, physical inactivity, and family history. A history of umbilical artery catheterization increases the risk of developing hypertension from renovascular disease. Metabolic syndrome, a combination of insulin resistance, hypertension, and hyperlipidemia, may affect up to 50% of overweight adolescents.

Primary or essential hypertension is unrelated to a second systemic disease. Children diagnosed with primary hypertension are more likely to become adults with hypertension. Secondary hypertension results from endocrinologic, cardiac, neurologic, or other factors, such as exposure to certain drugs or poisons (Box 173.4). Children with significant hypertension will usually have an underlying renal (as in glomerulonephritis) or renovascular cause.

Clinical Features

There are a variety of clinical presentations of hypertension in children. Asymptomatic or mildly symptomatic hypertension may show up in routine vital signs measured in children in the ED for unrelated illnesses. Symptomatic children may have headaches, abdominal pain, irritability, or nosebleeds. Patients may have personality changes or difficulties in school.

Hypertensive pediatric patients may present with a variety of signs and symptoms. Health care providers should ask about joint pain or swelling (Henoch-Schönlein purpura), palpitations (electrolyte abnormalities), weight loss (hyperthyroidism), flushing of the skin (pheochromocytoma), and drug ingestion (cocaine, methamphetamine). Patients with a renal cause of hypertension may have peripheral edema, palpable kidneys, abdominal or flank bruise, or a UTI.

Severe elevations in blood pressures by age include a systolic blood pressure of 160 mm Hg or higher and diastolic blood pressure of 105 mm Hg or higher in children younger than 10 years, and systolic blood pressure 170 mm Hg or higher and diastolic blood pressure 110 mm Hg or higher in children older than 10 years. (Children with hypertension from coarctation of the aorta will have a blood pressure differential in their extremities; see Chapter 170.)

Children with hypertensive emergencies have evidence of end-organ damage, including acute neurologic changes or encephalopathy, pulmonary edema, myocardial ischemia, and proteinuria. The electrocardiogram may show signs of ischemia or ventricular hypertrophy. Chest radiography may reveal cardiomegaly or pulmonary edema. Although hypertensive emergencies require prompt treatment, overaggressive treatment can lead to worsening neurologic deficits due to relative hypotension.

Hypertensive encephalopathy symptoms include headache, vomiting, altered mental status, visual disturbances (including blurry vision and diplopia), and seizures or stroke. Papilledema, decreased retinal venous pulsations, and cranial nerve palsies may be found on examination. The diagnosis is confirmed when the symptoms and signs subside rapidly after the blood pressure is lowered. Headache alone, without any other associated symptoms or signs, generally is not considered to represent a hypertensive emergency.43

Diagnostic Considerations

Diagnostic Testing

Laboratory and radiologic studies performed in the ED can determine the cause of the hypertension and presence of a hypertensive emergency (Box 173.5). Initial laboratory tests should

Causes of Hypertension in Children

**PRIMARY**
Essential hypertension

**SECONDARY**

- **Renal**
  - Glomerulonephritis
  - Henoch-Schönlein purpura
  - Pyelonephritis
  - Obstruction or reflux
  - Polycystic kidney disease
  - Diabetic nephropathy
  - Trauma
  - Renal transplant or hemodialysis
  - Tubercous sclerosis
  - Systemic lupus nephritis

- **Endocrine**
  - Pheochromocytoma
  - Cushing’s syndrome
  - Congenital adrenal hyperplasia
  - Corticosteroid treatment
  - Hyperthyroidism
  - Neuroblastoma
  - Ovarian tumor

- **Cardiac**
  - Congestive heart failure
  - Coarctation of the aorta

- **Vascular**
  - Hemolytic-uremic syndrome
  - Kawasaki syndrome
  - Renal artery thrombosis or stenosis

**Neurologic**
Central nervous system tumor or infection
Central nervous system trauma or abuse
Increased intracranial pressure
Guillain-Barré syndrome

**Neoplastic**
Neuroblastoma
Wilms’ tumor
Pheochromocytoma
Adrenal carcinoma

**Drugs**
Corticosteroids
Cocaine
Sympathomimetics
Oral contraceptives
Phencyclidine
Beta-blocker or clonidine withdrawal
Lead, mercury

**Others**
Iatrogenic fluid overload
Volume overload from end-stage renal disease

BOX 173.5

Diagnostic Evaluation in Hypertensive Emergencies* in Children

**History**

- History of medications or drugs, or family history of cardiovascular disorders
- Symptoms of severe headache or chest pain
- Physical examination focused on acute neurologic changes, funduscopic abnormalities, pulmonary edema
- Urinalysis for significant protein
- Chest radiography for cardiomegaly or congestive heart failure
- Electrocardiography for ventricular hypertrophy

**Laboratory and Radiologic Tests to Consider**

- Urinalysis and urine culture
- Urine catecholamine assay
- Complete blood count with platelet count
- Blood smear
- Measurement of sodium, potassium, chloride, carbon dioxide, calcium, phosphorus, magnesium, uric acid levels
- Blood urea nitrogen and creatinine determinations
- Serum C3 complement assay, antistreptolysin O titer, antinuclear antibody assay
- Plasma renin level
- Computed tomography urography or IV pyelography
- Voiding cystourethrography
- Renal ultrasound scan
- Renal arteriography

*Evidence of end-organ damage.

---

include a CBC, electrolyte, BUN, and creatinine levels, urinalysis, urine culture, chest radiography, and electrocardiography.

**Differential Diagnoses**

See Box 173.4 for causes of pediatric hypertension. Disorders with presentations similar to hypertensive encephalopathy include meningitis, brain tumor, intracerebral hemorrhage, stroke, and uremia. These conditions, however, generally produce only a mild increase in the systolic blood pressure; CT or lumbar puncture can also help identify other disorders.

**Management**

The management of hypertensive emergencies is discussed in Chapter 74. The goal of treatment is to reduce the mean arterial blood pressure by 10% to 20% over several minutes to hours. Patients with headache and vomiting should have their blood

- Use with caution in liver patients.
- Use with caution in renal patients.
- Avoid in asthma, pulmonary edema, and heart block.
- Avoid in second and third trimesters of pregnancy.
- With inadequate response, re-administer loading dose or increase maintenance dose by 25–50 µg/kg/min every 5–10 min.
- Usual maintenance range: 50–500 µg/kg/min.
- Morphine may increase esmolol levels.
- Avoid in pregnancy.

Patients with persistently severe hypertension, but without evidence of end-organ damage, should be started on an antihypertensive agent in consultation with the child’s primary care physician or a pediatric nephrologist. Angiotensin-converting enzyme inhibitors (eg, 0.3–0.5 mg/kg/dose >12 months of age; maximum, 6 mg/kg/day) or calcium channel blockers (eg, nifedipine ER, 0.25–0.5 mg/kg/day; maximum, 3 mg/kg/day; up to 120 mg/day) are useful as first-line agents and usually are well tolerated. The child may be observed for 4 to 6 hours after administration of the medication for evaluation of effectiveness or complications.

### Disposition

Otherwise asymptomatic well-appearing children without severely elevated blood pressure can be referred without treatment to their primary care physician for further evaluation and management. A child with evidence of a hypertensive emergency (ie, acute end-organ damage) should be admitted for vital sign monitoring, further evaluation, and treatment of hypertension.

### HENOCH-SCHÖNLEIN PURPURA

#### Principles

Henoch-Schönlein purpura (HSP) is an immunoglobulin A-mediated systemic vasculitis involving the small blood vessels of the skin, gastrointestinal tract, and joints. Immune complex deposition results in a systemic vasculitis, with up to 33% of patients experiencing recurrences. The peak incidence for HSP is between 4 and 7 years of age, with an overall occurrence rate of 13.5 episodes/100,000 children annually. Approximately 50% of affected children have a history of previous upper respiratory tract infection, and as many as 75% have group A beta-hemolytic streptococci cultured from the oropharynx. Other theorized predisposing factors include exposure to cold weather, certain foods, drugs, and insect bites. Other possible precipitants include varicella-zoster virus, Mycoplasma species, parvovirus, Campylobacter enteritidis, parvovirus B19, and Epstein-Barr virus.

### Clinical Features

The hallmark of HSP is a palpable, purpuric, or petechial rash. The rash is seen in the vast majority of patients and is most prominent on the lower extremities, starting at the lateral malleolus and extending to the buttocks. Arthralgia and arthritis are common, usually involving the knee and ankle joints. Dull periumbilical pain resulting from bleeding into the intestinal wall occurs in at least 50% of patients. In up to 50% of patients, abdominal pain or arthritis can be the only initial complaint. A self-limited glomerulonephritis will develop in 25% to 50% of children, manifested by hematuria with or without red blood cell casts. Children with acute renal failure, nephrotic syndrome, or hypertension are at higher risk of persistent renal manifestations. Testicular involvement occurs in up to 35% of male patients and may present with severe scrotal edema that resembles acute testicular torsion.

### Diagnostic Considerations

#### Diagnostic Testing

The classic HSP rash is usually diagnostic. Urinalysis should be ordered to screen for hematuria, RBC casts, and proteinuria; BUN and creatinine levels should be ordered if the urinalysis is significantly positive. CBC and coagulation studies should be considered in patients with severe skin involvement or distribution atypical for HSP. Patients with significant abdominal pain, especially with signs of obstruction or peritonitis, should undergo abdominal ultrasound to evaluate for intussusception; ultrasound findings may include intraluminal hematomas, duodenal wall thickening, and peritoneal fluid.
Differential Diagnoses

Purpura may also be seen in meningococcemia, Rocky Mountain spotted fever, HUS, and other vasculitides. Polycystic joint swelling can be seen with juvenile rheumatoid arthritis and systemic lupus erythematosus.

Management

The treatment of HSP is controversial because most cases resolve spontaneously and do not require therapy. NSAIDs can be used to treat joint pain, but renal function should be monitored. Corticosteroids have been shown to be effective in reducing the time to resolution of severe abdominal pain (eg, prednisone, 1–2 mg/kg/day; maximum, 60–80 mg/day). Corticosteroids do not reduce the risk of abdominal or renal complications.49–51

Disposition

Patients with only the skin manifestations of HSP can be discharged home, with close follow-up. NSAIDs or acetaminophen are recommended for joint pain and malaise. Patients with moderate to severe abdominal pain, multiple joint arthritis or inability to ambulate, proteinuria or evidence of gastrointestinal bleeding, or renal involvement should be admitted.49–51

HEMOLYTIC-UREMIC SYNDROME

Principles

HUS, a microangiopathic hemolytic anemia, is one of the most common causes of acute kidney injury in children. HUS is rare after 5 years of age, but recurrent HUS is more common in older children and is associated with a 30% mortality rate. In the United States, the most common cause is Shiga toxin (verotoxin)—producing \textit{E. coli} (STEC), specifically serotype O157:H7.50 Transmission is through person to person contact or exposure to contaminated food, such as unpasteurized dairy products or beef. HUS can be classified as primary (or atypical) HUS, caused by compliment dysregulation, and secondary HUS, caused by infections (eg, STEC, \textit{Shigella} organisms, \textit{S. pneumoniae}, \textit{Aeromonas}, or HIV), drugs (eg, chemotherapeutic or transplant antirejection drugs), or other idiopathic causes (eg, pregnancy, lupus). UTIs have also been implicated.

Renal compromise is due to renal vascular endothelial injury, often induced by viral or bacterial agents. RBCs are injured within narrowed blood vessels, resulting in a microangiopathic hemolytic anemia. Platelets, complement, and fibrin are deposited in the glomerular lumen, resulting in thrombocytopenia, a decrease in the glomerular filtration rate, and renal failure.

Clinical Features

Secondary HUS due to STEC presents with watery diarrhea, crampy abdominal pain, and occasionally fever. Within days of symptom onset, patients experience increasing abdominal pain, with 50% to 85% developing bloody stools. Patients may also develop toxic megacolon, ischemic colitis, intussusception, perforation, or delayed colonic stricture. Patients with a pneumococcal cause for the HUS typically present with pneumonia or, less commonly, meningitis, bacteremia, sinusitis, or otitis media.

Up to 10% of patients will experience the triad of sudden onset hemolytic anemia, thrombocytopenia, and acute renal insufficiency, with possible progression to renal failure. Up to 60% of diarrhea-associated HUS cases require dialysis, and death or end-stage renal disease was found to occur in 12%. Dehydration on admission increases the risk of renal failure.51 Pancreatic insufficiency resulting in insulin-dependent diabetes mellitus is a less common complication. Patients may develop central nervous system irritability; 40% develop seizures. Hypertension occurs in up to 50% of patients and may contribute to the development of encephalopathy.

Diagnostic Considerations

Diagnostic Testing

A family member with a concurrent history of HUS suggests an infectious source; a remote family history of HUS or previous episode of HUS suggests a genetic or complement-mediated source. Initial diagnostic laboratory tests include CBC, peripheral blood smear, urinalysis, and electrolyte, C-reactive protein, BUN, and creatinine levels. Leukocyte counts and C-reactive protein levels are significantly higher in patients with Shiga toxin–producing \textit{E. coli} O157:H7. The peripheral blood smear shows microangiopathic changes such as schistocytes, teardrop cells, or fragmented RBCs. WBC counts may be elevated, and the platelet count may be less than 50,000/µL. The hemoglobin level is typically less than 8 g/dL but can be as low as 5 g/dL as a result of the rapid hemolysis that occurs. Renal involvement can range from simple hematuria and proteinuria to severe renal failure, with elevated BUN and creatinine levels. Additional testing may include coagulation studies to differentiate other diagnoses (eg, disseminated intravascular coagulation [DIC]), Shiga toxin testing of stool, stool culture, and serologic studies for STEC serotypes.

Differential Diagnoses

The differential diagnosis of HUS includes systemic vasculitides, thrombocytopenic thrombotic purpura (rare in children), DIC, and nonmicroangiopathic causes of hemolytic anemia.

Management

With supportive therapy and early peritoneal dialysis, current mortality rates are less than 5%. Patients with evidence of dehydration should be resuscitated with NS, looking for improvement in mental status, heart rate, peripheral perfusion, and metabolic acidosis. Hyperkalemia is common and should be treated based on the potassium level and electrocardiographic findings (see Chapter 117). Patients with severe hyperkalemia, hyperphosphatemia, or severe metabolic acidosis should undergo dialysis.

Patients should receive packed RBCs (5 mL/kg during 4 hours) if the hemoglobin level falls below 6 g/dL. Platelet transfusions should be given for life-threatening bleeding or before an invasive procedure. Hypertension is responsive to calcium channel blockers (eg, nifedipine ER, 0.25–0.5 mg/kg/day PO; maximum, 3 mg/kg/day, up to 120 mg/day), beta blockers (eg, labetalol, 1–3 mg/kg/day), or nitroprusside (maximum dosing 12 mg/kg/day up to 1200 mg/day), or nitroglycerin (0.3–0.5 µg/kg/min IV; maximum, 10 µg/kg/min) for refractory cases. Seizures typically respond to benzodiazepines and phenytoin, but may require 3% saline (3–5 mL/kg) if secondary to hyponatremia. Antimotility agents may lead to toxic megacolon and should not be used. Antibiotics have not been shown to prevent HUS.52 In STEC, antibiotics may enhance the release of verotoxin from bacteria and should be avoided. Pneumococcal-associated HUS often presents with pneumonia and should be treated with appropriate antibiotics (eg, ceftriaxone, 50 mg/kg IV q24h; maximum, 2 g/dose; and vancomycin, 15 mg/kg IV qid; maximum, 2 g/dose). Hyperglycemia, ketonemia, and acidosis secondary to pancreatic islet cell necrosis are managed with insulin therapy.
Although of unproven benefit, plasmapheresis may be used for patients with severe neurologic involvement (eg, stroke). Renal dialysis and renal transplantation may be required, although primary HUS can recur in the transplanted kidney.

Patients with primary HUS renal damage appear to see improvement in their renal function when treated with the complement inhibitor eculizumab.53

Disposition
Patients with HUS should be admitted to the hospital, with pediatric nephrology consultation. Early dialysis and supportive therapy result in return to baseline renal function in up to 90% of patients with acute renal failure.52

KEY CONCEPTS

Priapism
• In low-flow priapism, cavernosal aspiration plus irrigation has been effective when performed within the first 48 hours, and preferably within a few hours, of symptom onset. Phentolamine, phenylephrine, ephedrine, or 1:1,000,000 epinephrine can be added to the irrigation solution used in performing corporal aspiration.

Phimosis and Paraphimosis
• Steroid cream is first-line therapy for phimosis. In paraphimosis, most can be reduced utilizing a number of techniques, only in severe cases involving vascular compromise of the glans penis, may a dorsal slit procedure may be necessary.

Testicular Torsion
• Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, a necrotic, gangrenous testis.
• Color Doppler ultrasonography is the test of choice, but false negatives due occur.
• Testicular salvage rates are 96% if detorsion is performed less than 4 hours after symptom onset; with more than a 24-hour delay, the salvage rate falls to less than 10%.

Varicoceles
• Left-sided varicoceles account for 85 to 95% of the cases.
• Right-sided varicoceles are often caused by inferior vena cava thrombosis or compression by tumors.

Urinary Tract Infections
• In children younger than 2 years, a urinalysis alone is inadequate to rule out a urinary tract infection; urinalysis yields false-negative results in 10%–50% of patients. Urine cultures should be sent in children less than 2 years of age.
• Girls less than 2 years old, and boys, uncircumcised, less than 1 year, and circumcised less than 6 months are at higher risk for UTIs.
• Children less than 2 years old should be considered to have upper tract disease and receive antibiotic treatment for 7–14 days.

Renal Stones
• Renal stones are more common than ureteral stones in younger children.
• Older children can present with classic renal stones signs and symptoms; younger children may present with more non-specific symptoms, such as malaise and non-tender abdominal pain.

• Ultrasound should be the first-line imaging modality used in children with suspected renal stones.

Poststreptococcal Glomerulonephritis
• Patients will present with a history of a pharyngeal or skin infection in the previous 2–6 weeks; clinical findings are usually limited to the urinary tract including hematuria, flank pain or sometimes generalized edema.
• Diagnostic testing will show blood, protein, and RBC casts in the urine; evidence of renal dysfunction (elevated BUN) and low complement levels will also be found.
• Treatment includes restricting fluid and diuretics for more significant disease.

Nephrotic Syndrome
• Albumin and immunoglobulin levels are typically both decreased in nephrotic syndrome.
• Clinical signs include periorbital edema, weight gain, and more serious signs such as pulmonary edema or ascites.
• Children with nephrotic syndrome are at increased risk for thrombosis and bacterial infections, especially Streptococcus and E. coli.
• Treatment includes corticosteroids and diuretics.

Henoch-Schönlein Purpura (HSP)
• HSP is an immunoglobulin A-mediated systemic vasculitis that involves the skin, GI tract, joints, and kidneys.
• Urinalysis may be positive for blood and RBC casts.
• Corticosteroids can be useful for severe abdominal pain.

Hemolytic-Uremic Syndrome (HUS)
• HUS is a microangiopathic hemolytic anemia found in young children. In the U.S., it is typically related to Shiga-toxin producing E. coli (STEC), presenting with abdominal pain and bloody diarrhea. Streptococcus pneumoniae has also been implicated.
• Renal vascular endothelium injury results in renal insufficiency and damage to RBCs; glomerular damage occurs due to platelet, complement, and fibrin deposits.
• Peripheral smear will show damaged RBCs and typically thrombocytopenia; renal involvement ranges from hematuria to elevated BUN and creatinine.
• Stool cultures and Shiga toxin testing should be sent in diarrhea-associated cases.
• Antibiotics are not indicated in HUS unless a concurrent presumptive pneumococcal infection such as pneumonia is present.

CHAPTER 173: QUESTIONS & ANSWERS

173.1. A 12-year-old boy presents with engorgement of the dorsal corpora cavernosa. You expect to elicit which of the following in his history?

A. Recent sexual intercourse
B. Recent trauma
C. Sexual abuse
D. Sickle cell disease
E. Testicular mass

Answer: D. Priapism is the engorgement of the dorsal corpora cavernosa, resulting in dorsal penile erection and ventral penile flaccidity. Sickle cell disease and leukemia are responsible for most cases in children.

173.2. A 17-year-old uncircumcised adolescent presents complaining of pain and swelling of his penis. On physical examination, you find a grossly edematous glans and distal shaft, with a retracted prepuce that is unable to be reduced. There is evidence of cellulitis. Compression and manual reduction have been unsuccessful. What is the next step in the management of this patient?

A. Administer local anesthesia, lubrication, and forceful reduction.
B. Perform a dorsal slit followed by admission to the hospital.
C. Prescribe oral antibiotics and follow-up in 24 hours.
D. Prescribe topical antibiotics and antifungal agents and follow-up in 1 week.

Answer: B. Paraphimosis is the inability to retract the foreskin over the glans and represents a true urologic emergency. Ice, circumferential compression, and manual reduction are all ways to reduce the foreskin. If all attempts fail, urologic consultation and circumcision or a dorsal slit procedure may be necessary. Any evidence of cellulitis or necrosis warrants admission to the hospital, intravenous antibiotics, and urologic consultation. To achieve pain control using a local procedure, a dorsal penile nerve block should be attempted. Injection of anesthetic to the glans will add protection against pain.

173.4. A 13-year-old boy presents with pain, swelling, and discoloration of his left testicle. Prior to the testicular changes, he had a fever and mild facial swelling. What is the most appropriate next best step in the management of this patient?
A. Admission for antibiotics and serial examinations
B. Color flow Doppler ultrasound
C. Inquiry about sexual encounters
D. Pain management and reassurance
E. Urology consult for surgical management

Answer: B. During the course of mumps, orchitis usually develops after the first week and presents with tenderness and edema of the testis, with discoloration of the scrotum. With the limited information in this case, it is not clear that this patient does not have testicular torsion. Doppler ultrasound may be necessary to distinguish orchitis from testicular torsion. For patients with a clear viral origin such as mumps, treatment is aimed at pain control (eg, scrotal elevation, nonsteroidal antiinflammatory drugs, possibly narcotics).

173.5. Which of the following statements about testicular torsion is false?
A. Indeterminate ultrasound requires urology consult.
B. Intravaginal torsion results from rotation of the testis inside the tunica vaginalis.
C. Most patients with testicular torsion are infants.
D. Predilection for torsion exists if the tunica vaginalis completely covers the testis.
E. The presence of the cremasteric reflex does not preclude torsion.

Answer: C. Most patients are adolescents, although testicular torsion can be seen at any age. If the tunica completely covers the testis and attaches higher up on the spermatic cord, proper testicular fixation does not occur and there is a predisposition to torsion. In intravaginal torsion, the testicle may rotate within the tunica vaginalis and thereby constrict the arterial blood flow. The presence of the cremasteric reflex does not preclude testicular torsion. Results of a urinalysis are rarely helpful because pyuria can be seen in cases of testicular torsion and epididymitis. In cases of indeterminate ultrasound results, the urology consultant should be notified for disposition decisions.

173.6. A mother brings in her 2-year-old child after she noticed a pink tinge on the diaper when she was changing her child. Which of the following is not part of the differential diagnosis?
A. Blueberry ingestion
B. Henoch-Schönlein purpura
C. Red apple ingestion
D. Serratia marcescens
E. Urate crystals

Answer: C. Not all red urine contains blood. Certain drugs or foods, such as phenothiazines, ibuprofen, beets, and blueberries, can cause reddish-colored urine; apples, however, do not. In neonates, urate crystals can cause red-tinted urine in the diaper. Serratia marcescens, a fecal pathogen, can cause a red pigmentation when left in the diaper. Bleeding from the vagina or rectum can sometimes be mistaken for blood in the urine. Systemic illnesses such as Henoch-Schönlein purpura and hemolytic-uremic syndrome can cause hematuria.

173.7. A 5-year-old boy presents with flank pain and hematuria. He was recently treated with penicillin for a throat infection. Urinalysis demonstrates blood, protein, and red blood cell casts. Which test will be most helpful in establishing a diagnosis in this patient?
A. ASO titer
B. Complement levels
C. Hyaline casts
D. Serum sodium and osmolarity
E. Urine electrolytes

Answer: A. This is likely poststreptococcal glomerulonephritis. The ASO and immunoglobulin G levels should be elevated. Total complement levels, especially C3, are decreased in most patients during the first 2 weeks of the illness. The complement levels should return to normal within 3 or 4 weeks. The blood urea nitrogen (BUN) level is elevated; hyponatremia and hyperkalemia may also be present.
CHAPTER 173 Genitourinary and Renal Tract Disorders

the lateral malleoli and extending to the buttocks. Therapy for patients with severe renal involvement also includes intravenous immunoglobulins, although promising results have also been seen in patients with severe abdominal pain.

173.9. A 3-year-old girl presents with watery diarrhea and crampy abdominal pain. Her vital signs are blood pressure 130/80 mm Hg, heart rate 100 beats/min, respiratory rate 13 breaths per minute, and temperature 38.0°C (100.4°F). The diarrhea has been present for a number of days and has just turned bloody, which prompted the visit today. Laboratory assessment reveals hemoglobin, 6 g/dL, potassium, 6.1 mEq/L, blood urea nitrogen, 40 mg/dL, and creatinine, 2.5 mg/dL. Which of the following tests is most likely to aid in the diagnosis of this patient?

A. Blood cultures  
B. Leukocytosis  
C. Peripheral smear with schistocytes  
D. Stool cultures  
E. Thrombocytosis  

Answer: C. The patient has hemolytic-uremic syndrome, which is one of the most common causes of acute renal failure in children. It usually involves infants and children, with a mean age at presentation of 3 years, but is rare after 5 years of age. The peripheral blood smear shows microangiopathic changes such as teardrop cells, helmet cells, microspherocytes, and burr cells.
Acute presentations of neurologic dysfunction reflect a primary nervous system abnormality or a secondary manifestation of underlying disease. In children, associated history and physical examination findings, as well as diagnostic considerations, are unique and often markedly different than those in adults. This chapter is directed at understanding the pathophysiology and significant clinical features of major neurologic presentations in children. Information will be organized by the most salient clinical manifestations of pediatric neurologic disorders—altered mental status, seizures, headache, ataxia and derangements of balance, and motor dysfunction (Table 174.1).

**ALTERED MENTAL STATUS**

**Principles**

Altered mental status is a common and often puzzling pediatric presentation. Groupings of possible causes include vascular events (eg, stroke, arteriovenous malformation with bleed), infection (eg, meningitis, sepsis, encephalitis), trauma, toxic ingestion, anatomic or structural abnormality (eg, intracranial mass or tumor), metabolic derangements, intussusception, or seizures, which may be subclinical. Individual diagnoses associated with altered mental status will not be explored in full detail in this chapter. However, a guideline for approaching and managing patients in the emergency department (ED) with altered mental status will be presented.

**Clinical Features**

Altered mental status in children has a varied spectrum of clinical presentations and may include abnormalities in cognition, behavior, or memory. In children, these are manifested as an altered level of consciousness, excessive sleepiness, irritability, lethargy, or abnormal behavior. The nature of the altered mental status, as well as the time course and concurrent findings, such as fever or focal neurologic signs, are pivotal in evaluating these patients. Information obtained in the history may be critical to diagnoses of trauma, toxic ingestion, atypical migraine, or infection.

During the initial assessment of an altered infant or child, vital signs can be essential to understanding the underlying diagnosis. Heart rate, blood pressure, and respiratory rate, for example, may provide information about conditions such as toxic ingestion, elevated intracranial pressure (ICP), or metabolic derangements such as diabetic ketoacidosis. Level of consciousness may be readily assessed using the AVPU scale: alert (alert and spontaneously interactive), verbal (responds to verbal cues), painful (responds only to painful stimuli), unresponsive (unresponsive to all external stimuli). Additionally, identifying focal neurologic deficits and the presence or absence of fever promptly will aid the health care provider in the diagnostic evaluation.

Special consideration should be given to meningitis in the altered infant or child because presenting signs of meningitis vary widely by age and classic symptoms (eg, vomiting, headache, bulging fontanel, nuchal rigidity) may not be sufficient to guide diagnostic evaluation. Neonates, for example, may or may not have a fever—the absence of fever does not eliminate the possibility of a serious bacterial illness because more than 50% of neonates with meningitis are afebrile or exhibit hypothermia—and often demonstrate vague findings such as poor feeding and increased sleepiness and fussiness in addition to abnormal vital signs. Tachycardia, bradycardia, tachypnea, or apnea are not uncommon. Older infants may show more visible signs of behavioral changes, including decreased social interaction. In children, common findings include fever, headache, vomiting, stiff neck, lethargy, and obtundation. Skin findings of diffuse petechiae and purpura in the ill-appearing pediatric patient should raise a high clinical suspicion for bacterial meningitis. In the ill-appearing or altered infant younger than 3 months, clinical signs are often nonlocalizing and can therefore present a diagnostic challenge. In this age group, there are few distinguishing features to differentiate sepsis from meningitis, metabolic derangements, or an acute abdomen.

**Diagnostic Considerations**

**Differential Diagnoses**

The breadth of differential diagnoses associated with altered mental status in children, by definition, involves a broad spectrum of potential management interventions in the ED. The mnemonic AEIOUTIPS, as outlined in Box 174.1, can assist the emergency clinician in the differential diagnosis and determining priorities for management.

**Diagnostic Testing**

After evaluation and stabilization of the airway, breathing, and circulation, priorities of the emergency clinician include obtaining a bedside glucose test, rapid IV access, and laboratory values, including a full panel of electrolytes. Rapid bedside testing, such as with iStat, can be performed to assess for abnormalities in sodium, potassium, and lactate levels and determine pH. A complete blood count (CBC) and blood culture may also be sent if an infectious cause is suspected, and determining venous blood gases and lactate level can be helpful in assessing acid-base status. Toxicology screens may be warranted in many cases. The decision to obtain head imaging—by computed tomography (CT) or magnetic resonance imaging (MRI)—rapidly in the ED is made based on the presence of focal neurologic deficits, in conjunction with a history and examination suggestive of an acute intracranial process.

Special consideration should be made regarding the need for more invasive diagnostic procedures such as lumbar puncture (LP) in this setting. Bacterial meningitis is a medical emergency that may present with altered mental status, and all children with suspected bacterial meningitis should have a lumbar puncture performed unless it is contraindicated. Contraindications to an LP include signs of elevated ICP, focal neurologic deficits on examination, and underlying coagulopathy. Antibiotic therapy for
the patient with suspected bacterial meningitis should not be delayed by an LP.

Due to the difficulties in assessing ill-appearing infants younger than 3 months, a broad initial evaluation may be necessary for altered mental status in this population, including CBC, chemistries, LP, and pan cultures (blood, urine, and cerebrospinal fluid [CSF]). It is important to note that in the case of the ill-appearing infant, blood cultures and LP should be undertaken concomitantly due to the increased risk of serious bacterial infection in this population, including bacteremia and meningitis. For older infants and children, the risk of bacterial meningitis may be evaluated using clinical prediction rules based on laboratory results.

Additionally, if the history or physical examination raises any concern for an acute abdominal process, abdominal ultrasound should be performed to evaluate for intussusception because its presentation is often nonspecific and can resemble that of meningitis or sepsis.

**Management**

After the initial resuscitation, including stabilization of the airway, breathing, and circulation, data obtained by the history, physical examination, and early laboratory values often dictate the first steps in management. If there is a known toxic ingestion, efforts will quickly be directed at the correction of perturbations associated with the offending agent and, if indicated, toxin removal. If initial laboratory values indicate hyperglycemia, hypoglycemia, or other electrolyte imbalances, early measures should be aimed at correcting these. The abdominal examination may reveal a surgical abdomen as the cause of altered mental status, necessitating the need for ultrasound, CT, or direct surgical consultation. Head imaging, if performed, may also guide early management steps further.

A lumbar puncture is indicated in any child for whom bacterial meningitis is suspected. Antibiotic therapy in the ED should not be delayed by an LP in a case of highly suspected bacterial meningitis. Additionally, initial antibiotic coverage should be broad and guided by the most likely pathogens in the patient’s age group (Tables 174.2 and 174.3). Pretreatment with antibiotics in patients with bacterial meningitis is associated with higher CSF glucose levels and lower CSF protein levels, but does not alter the CSF white blood cell count, absolute neutrophil count, or polymerase chain reaction (PCR) results. Over time, antibiotics will affect sensitivity of CSF cultures, but this does not justify treatment delay. The role of steroids, particularly dexamethasone, in conjunction with antibiotic therapy for the treatment of acute bacterial meningitis, is controversial. It is therefore best to adhere to the latest recommendations of the American Academy of Pediatrics (AAP) and limit the use of dexamethasone to the presumptive treatment of pneumococcal meningitis in infants older than 6 weeks after consideration of the potential benefits and risks. The AAP has suggested that dexamethasone may also be beneficial for infants and children with *Haemophilus influenzae* meningitis to decrease the risk of neurologic sequelae, including hearing loss, if given before or concurrently with the first dose of an antimicrobial agent.

In this setting, a child’s immunization history, as well as the CSF Gram stain results, may serve to guide the appropriate use of steroids.

When bacterial meningitis is in the differential diagnosis of altered mental status, but not highly suspected, it is reasonable to consider risk stratification of the patient to determine if antibiotics can be withheld until further information (eg, CSF white cell count) is obtained. Finally, acyclovir should be administered to an

Seizures are the most common pediatric neurologic disorder; up to 10% of children suffer at least one seizure in the first 16 years of life, most of which are febrile seizures. A seizure is defined as a paroxysmal event characterized by temporary involuntary changes in the patient caused by abnormal and excessive activity of a group of cortical neurons. The clinical manifestations of the seizure depend on the location and extent of brain involvement and may include alterations in behavior, motor activity, level of consciousness, or autonomic function. Seizures are classified as provoked or unprovoked. Provoked seizures are caused by an identifiable trigger and stem from a broad array of disturbances, including fever, metabolic derangements, and trauma. Unprovoked seizures have no clear immediate precedent. Epilepsy is commonly defined as the occurrence of two or more unprovoked seizures.

The underlying pathophysiologic feature of all seizures is excessive, synchronous electrical neuronal discharge. Infants and children younger than 5 years are thought to be more susceptible to seizures due to an immature nervous system, in which excitatory neuronal activity predominates and inhibitory systems are undeveloped. A paucity of synaptic connections and alterations in the synthesis of neurotransmitters may play a role in a child’s susceptibility to seizures.

Clinical Features

In the presence of ongoing seizure activity, resuscitation measures to ensure a patent and protected airway, stable circulation, and seizure control should be initiated. To determine whether an event was truly a seizure, the initial assessment should include an effort to obtain a description from an eyewitness. The history should include any known risk factors for epilepsy or prior seizures, details leading up to the event, a full description of the episode itself (including nature of body movements, duration, and associated symptoms, such as urinary incontinence), and characterization of the moments immediately following the event, with special attention to mental status, event recall, and lethargy or confusion. If the patient has a known seizure disorder, recent medication changes—including new medications as well as dose or interval adjustments of existing medications—should be identified, as well as missed or extra doses.

The physical examination should concentrate on signs of systemic disease that can cause seizure, including evidence of meningitis, trauma, drug ingestion, dehydration, hypertension, and heart disease. Skin lesions, such as café au lait spots or hypopigmented nevi, may indicate a neurocutaneous disorder. An abnormal head circumference may indicate hydrocephalus or abnormal brain growth. A careful neurologic examination should assess for signs of increased ICP and focal neurologic deficits.

If the presenting signs and symptoms are consistent with seizure activity, the seizure can then be classified by type and a cause pursued. Seizures are classified into two main types, partial (consciousness is maintained) and generalized (consciousness is lost; Table 174.4).

There are two types of partial, or focal, seizures, complex and simple. In complex partial seizures, the patient experiences a change in level of awareness and may exhibit bizarre behaviors, including staring, lip smacking, wandering, or picking at clothing. In simple partial seizures, the patient experiences no change in mentation. An important subcategory of focal seizures is composed of benign focal epilepsies of childhood, which are functional in nature; that is, they do not result from abnormalities in brain structure or injury to the brain. Benign focal epilepsies spontaneously resolve over time; benign childhood epilepsy with centrotemporal spikes (also called benign rolandic epilepsy) is most common and represents 10% to 20% of all childhood epilepsies.5,6

Generalized seizures may be convulsive or nonconvulsive. A convulsive seizure may start focally and generalize secondarily.

Seizures are the most common pediatric neurologic disorder; up to 10% of children suffer at least one seizure in the first 16 years of life, most of which are febrile seizures. A seizure is defined as a paroxysmal event characterized by temporary involuntary changes in the patient caused by abnormal and excessive activity of a group of cortical neurons. The clinical manifestations of the seizure depend on the location and extent of brain involvement and may include alterations in behavior, motor activity, level of consciousness, or autonomic function. Seizures are classified as provoked or unprovoked. Provoked seizures are caused by an identifiable trigger and stem from a broad array of disturbances, including fever, metabolic derangements, and trauma. Unprovoked seizures have no clear immediate precedent. Epilepsy is commonly defined as the occurrence of two or more unprovoked seizures due to an immature nervous system, in which excitatory neuronal activity predominates and inhibitory systems are undeveloped. A paucity of synaptic connections and alterations in the synthesis of neurotransmitters may play a role in a child’s susceptibility to seizures.

Clinical Features

In the presence of ongoing seizure activity, resuscitation measures to ensure a patent and protected airway, stable circulation, and seizure control should be initiated. To determine whether an event was truly a seizure, the initial assessment should include an effort to obtain a description from an eyewitness. The history should include any known risk factors for epilepsy or prior seizures, details leading up to the event, a full description of the episode itself (including nature of body movements, duration, and associated symptoms, such as urinary incontinence), and characterization of the moments immediately following the event, with special attention to mental status, event recall, and lethargy or confusion. If the patient has a known seizure disorder, recent medication changes—including new medications as well as dose or interval adjustments of existing medications—should be identified, as well as missed or extra doses.

The physical examination should concentrate on signs of systemic disease that can cause seizure, including evidence of meningitis, trauma, drug ingestion, dehydration, hypertension, and heart disease. Skin lesions, such as café au lait spots or hypopigmented nevi, may indicate a neurocutaneous disorder. An abnormal head circumference may indicate hydrocephalus or abnormal brain growth. A careful neurologic examination should assess for signs of increased ICP and focal neurologic deficits.

If the presenting signs and symptoms are consistent with seizure activity, the seizure can then be classified by type and a cause pursued. Seizures are classified into two main types, partial (consciousness is maintained) and generalized (consciousness is lost; Table 174.4).

There are two types of partial, or focal, seizures, complex and simple. In complex partial seizures, the patient experiences a change in level of awareness and may exhibit bizarre behaviors, including staring, lip smacking, wandering, or picking at clothing. In simple partial seizures, the patient experiences no change in mentation. An important subcategory of focal seizures is composed of benign focal epilepsies of childhood, which are functional in nature; that is, they do not result from abnormalities in brain structure or injury to the brain. Benign focal epilepsies spontaneously resolve over time; benign childhood epilepsy with centrotemporal spikes (also called benign rolandic epilepsy) is most common and represents 10% to 20% of all childhood epilepsies.5,6

Generalized seizures may be convulsive or nonconvulsive. A convulsive seizure may start focally and generalize secondarily.
The most common type of generalized nonconvulsive seizures is absence seizures. Absence seizures are marked by a brief arrest of consciousness and movement, typically lasting 5 to 30 seconds; no postictal drowsiness occurs. It may be difficult to differentiate a brief complex partial seizure, in which a child may stare and not respond, from an absence seizure.

The frequency of seizures is higher in the first month of life than at any other time in childhood. Neonatal seizures may be subtle; apnea, sustained eye deviation, chewing, or limb bicycling movements may be the only apparent signs. There is a high incidence of subclinical electroencephalographic seizures in this population. Focal clonic movements are often associated with an underlying structural lesion. Although there are many causes of neonatal seizures, relatively few account for most cases. These include hypoxic-ischemic encephalopathy, intracranial infection, congenital brain malformation, cerebrovascular events, electrolyte disturbances, metabolic derangements, and nonaccidental trauma.

Seizures can be further divided into three main categories—acute symptomatic, remote symptomatic, and idiopathic seizures (Table 174.5). Acute symptomatic seizures are provoked by an acute event such as fever. Remote symptomatic seizures are due to a preexisting or remote central nervous system (CNS) lesion such as cerebral palsy or a congenital brain malformation. Idiopathic seizures have no identifiable cause.

Categories of Seizures

Acute Symptomatic Seizures

Fever is the most common cause of acute symptomatic seizures affecting up to 5% of children. A febrile seizure is defined as a seizure occurring in the presence of fever without CNS infection or other cause. A simple febrile seizure is generalized, lasts less than 15 minutes, and occurs in a neurologically and developmentally normal child between 6 months and 6 years of age.

Simple febrile seizures typically occur early in the course of illness. Temperature does not need to be markedly elevated; almost 50% of children with a febrile seizure have a documented temperature below 39°C (102.2°F). Complex febrile seizures are diagnosed when multiple seizures occur during the same illness, the seizures are longer than 15 minutes, or the seizures have a focal component.

Meningitis should be considered in any patient with seizures and fever, although a child whose mental status is normal before and after the seizure is very unlikely to have meningitis. We recommend evaluation and treatment for meningitis in infants younger than 3 months presenting with febrile seizures. They are not only at higher risk for serious bacterial infections, including meningitis, but their mental status is difficult to assess accurately.

Inborn errors of metabolism and metabolic or electrolyte derangements are also a common cause of seizures in children. Hypoglycemia, hyponatremia, and hypernatremia are associated with seizures. Dehydration is the most common cause of hypernatremia. Hypocalcemia and hypomagnesemia may lead to muscle spasms, paresthesias, hyperactive reflexes, weakness, tetany, or seizures. Hypocalcemic seizures are a common cause of neonatal seizures.

Posttraumatic seizures occur in as many as 15% of children after head injury. Impact seizures, occurring within 1 hour of a head trauma, are not associated with significant injury or with the development of epilepsy. It may be difficult to distinguish these from seizures associated with intracranial injury, and a CT scan of the head without contrast enhancement should be considered. Early posttraumatic seizures, occurring within the first week of injury, may arise from cerebral edema or intracranial hemorrhage or contusion.

Brain tumors cause a wide variety of symptoms, depending on their location and type of tumor. Infratentorial tumors, the most common location in the pediatric population, do not typically cause seizures.

Although rare, a seizure may be the presenting sign of stroke. Congenital heart disease, sickle cell anemia, moyamoya disease, and homocystinuria are some of the major risk factors for ischemic stroke in children. Vascular malformations, such as arteriovenous malformations, may cause hemorrhagic stroke or subarachnoid hemorrhage.

Numerous drugs are known to cause seizures. Cyclic antidepressants, cocaine and other stimulants, antihistamines, and iso- niazid are the most common agents of drug-induced seizures. Seizures may occur during drug withdrawal, usually within 48 hours of drug cessation. Withdrawal of benzodiazepines and barbiturates leads to an abstinence syndrome similar to ethanol withdrawal.

Reflect seizures are precipitated by a specific, identifiable stimulus. For example, flashing lights on television or video games may induce seizures in photosensitive children.

Convulsive status epilepticus is a true neurologic emergency. It is associated with high morbidity and mortality rates that increase with the duration of seizure activity. For clinical practice purposes, status epilepticus is typically defined as 5 minutes or more of continuous seizure activity (clinical or electroencephalographic) or recurrent seizure activity without return to baseline between seizures. Although the diagnosis of convulsive status epilepticus usually is obvious, the duration of the seizures is often underestimated because the intensity of the jerking tends to diminish with time.

Status epilepticus occurs significantly more frequently in children than in adults, particularly in those younger than 1 year; febrile illness is the most common precipitant of status epilepticus in

Remote Symptomatic Seizures

Causes of remote symptomatic seizures include congenital brain malformations, neurocutaneous disorders, cerebral palsy, and neurodegenerative disease.

Diagnostic Considerations

Differential Diagnoses

Paroxysmal events that affect children and involve alterations in level of consciousness or motor activity may be confused with seizure activity (Table 174.6). Syncope is most commonly mistaken for a seizure; it is characterized by a sudden loss of consciousness and motor tone caused by a transient, global cerebral hypoperfusion. The patient will often complain of lightheadedness and blurred vision and may appear pale and sweaty prior to losing consciousness. Brief jerking movements are possible with syncope events, but should not be prolonged. Postictal confusion does not occur, but trembling and stiffening are common. Vasovagal syncope is common in otherwise healthy children and does not warrant further evaluation unless recurrent. Cardiogenic syncope, such as prolonged QTc syndrome, is potentially fatal. Syncope should be considered if there is no postictal period or tonic-clonic activity, if the event occurred during exercise, or if palpitations were present.

Breath-holding spells occur in up to 5% of children and are triggered by pain or emotional upset. The first episode usually occurs between the ages of 6 and 18 months, with episodes lasting up to 6 years of age. After a trigger, the child becomes pale or cyanotic and may lose consciousness, sometimes with a brief period of clonic movements or opisthotonos. The average attack lasts approximately 40 seconds. A history of recurrent episodes associated with crying may be helpful in distinguishing these from seizures or other apparent life-threatening events (ALTEs).

Migraines may mimic seizures, particularly when they are accompanied by an aura, motor dysfunction, clouding of consciousness, or vomiting.

Disorders of sleep are distinguished by excessive daytime sleepiness or by disordered nighttime sleep. In narcolepsy, daytime sleep attacks, sleep paralysis, hypnagogic hallucinations (vivid hallucinations while falling asleep), and cataplexy (sudden loss of motor tone) occur. Cataplexy may be mistaken for atonic or absence seizures. Nocturnal enuresis may raise concern for an unwitnessed nighttime seizure associated with incontinence. In night terrors (pavor nocturnus), the child suddenly wakes, crying inconsolably, and is relatively unresponsive. The child returns to sleep and does not typically recall the event. Sleepwalking (somnambulism) and sleep talking (somniloquy) are common among school-age children.

Movement disorders may mimic seizures. Tics are rapid, repetitive, brief involuntary movements that occur intermittently and in flurries. Those most commonly seen are eye blinking and head shaking. Patients do not lose consciousness. Sydenham’s chorea is an autoimmune-mediated systemic inflammatory response that occurs in association with a group A streptococcal pharyngitis infection. It typically manifests with irregular, non-rhythmic, involuntary jerking of the extremities and face and may present during the acute phase of the streptococcal infection or as a latent manifestation months after the initial illness. Shudder attacks are uncommon but are easily mistaken for seizures. The movement is that of the chill experienced when cold water runs down the back. Paroxysmal choreoathetosis is an abnormal motor movement that may be spontaneous or triggered by the child’s movement.

Behavioral or psychiatric disturbances can produce behaviors that may appear epileptic. Panic attacks may be mistaken for complex partial seizures. The patient has a sudden sensation of intense fear accompanied by shortness of breath, dizziness, palpitations, sweating, choking, chest discomfort, and fear of dying. Psychogenic seizures are involuntary events that mimic seizures.

Many children with psychogenic seizures also have epileptic seizures. Prolonged electroencephalographic monitoring may be necessary to differentiate an epileptic seizure from a psychogenic seizure.

Infants with gastrointestinal reflux may exhibit Sandifer’s syndrome, characterized by episodes of abnormal posturing, arching of the back, and torticollis.

Management

The initial management of any actively seizing child involves ensuring patency of the airway, adequate oxygenation and ventilation, and support of circulation. Oxygen should be applied via cannula or face mask and intravenous (IV) or intraosseous (IO) access quickly obtained. Monitoring end-tidal carbon dioxide may be helpful to assess ventilatory status. Patients with ongoing convulsions are at risk for hyperventilation and apnea, and intubation and mechanical ventilation may be necessary to prevent aspiration. Hyperventilation may also raise the risk for increased ICP.

Hypoglycemia causing seizures in infants and children is treated with an IV bolus of 10% dextrose, 2 mL/kg, with repeat boluses as needed to normalize the serum glucose level. Severe symptomatic hyponatremia may be treated with the administration
of 3% saline (2 mL/kg IV infused over 30 minutes) to raise the serum sodium level by 3 to 7 mEq/L. The remainder of the correction should occur slowly during the next 24 hours or more with the goal of correcting serum sodium levels by 6–8 mEq/L per 24-hour period. Hypernatremia is corrected slowly during 48 hours. Hypocalcemia is treated with 10% calcium gluconate, 100 mg/kg IV; the patient should be on a cardiac monitor during the infusion. Toxic ingestions are treated based on the specific toxin involved. Seizures caused by isoniazid (INH) poisoning are particularly resistant to standard seizure treatment, yet respond to pyridoxine. The dose of pyridoxine is 1 g IV for every gram of INH ingested. When the quantity of INH ingested is unknown, 5 g IV may be administered to an adult and 70 mg/kg (maximum, 5 g) to a child.

Status Epilepticus

Status epilepticus is a true medical emergency. The patient should be positioned to maximize ventilation and prevent aspiration. The cervical spine should be protected in a case of suspected trauma. Oxygen should be administered by nasal cannula or face mask. A large suction catheter should be available to suction oropharyngeal secretions. In younger patients, the tongue may obstruct the airway; a nasopharyngeal airway will keep the tongue forward and improve respiratory status. If facial trauma is present, a nasopharyngeal airway may be contraindicated.

If there is evidence of increased ICP, the airway is compromised, or respiratory failure occurs, the patient should be intubated. When clinically appropriate, short-acting neuromuscular blockers should be used to permit continued monitoring of seizure activity.

Heart rate, blood pressure, respiratory rate, and pulse oximetry should be monitored and hyperthermia treated with antipyretics and cooling blankets. An IV line should be placed and blood samples sent for electrolyte values, glucose concentration (including rapid blood glucose test), calcium and magnesium levels, renal function tests, liver function tests, antiepileptic levels (if indicated), and CBC. Urine should be sent for toxicology. Metabolic abnormalities should be corrected.

Anticonvulsant treatment should begin as quickly as possible (Fig. 174.1). Benzodiazepines, particularly lorazepam and diazepam, are the initial drugs of choice in the treatment of status epilepticus; they diffuse quickly into the CNS, rapidly terminating seizure activity 70% of the time. Hypotension,
Febrile Seizures

Children with simple febrile seizures do not require blood and urine testing other than as needed for the evaluation of fever source. According to newer AAP recommendations, LP is not necessary in children older than 12 to 18 months in whom clinical findings are not suggestive of meningitis. In immunized infants 6 to 18 months of age with a first-time simple febrile seizure, LP can be avoided if the child is not ill-appearing, has returned to baseline, and there are no clinical signs of meningitis. Additional consideration of the need for LP should be made for children between 6 and 12 months of age whose vaccination status for H. influenzae type b or Streptococcus pneumoniae is incomplete and in children who have been pretreated with antibiotics.

Electroencephalography and neuroimaging generally are not required after a first simple febrile seizure.

Afebrile Seizures

In many cases, the history and physical examination alone will serve to guide further testing. For infants and children older than 6 months who have had a first-time nonfebrile seizure and have returned to baseline, laboratory testing should be pursued in a targeted manner, based on clinical and historical findings. A seizure in the setting of recent diarrhea may warrant examination of serum chemistries for possible electrolyte abnormalities. All pediatric patients with a first-time afebrile seizure should have toxicology screening performed unless the history or examination strongly excludes this possibility. A lumbar puncture should be considered for patients presenting with unprovoked seizures who demonstrate persistent abnormal mental status, do not return to baseline, or show signs of meningitis. An outpatient EEG may be appropriate in well-appearing children who have returned to baseline.

Emergent neuroimaging should be performed in patients with new focal neurologic deficits, persistent altered mental status, recent trauma, persistent headache, or partial seizures. Infants and children who present in status epilepticus not related to fever should have neuroimaging. Children with generalized unprovoked seizures and normal examination findings on presentation do not necessarily require acute imaging. A focal abnormality on follow-up EEG may indicate a need for neuroimaging, which can be done on an outpatient basis. Children with a history of epilepsy do not need neuroimaging unless there is a change in clinical status.

If imaging is indicated in the acute period, CT or MRI may be used. Although MRI provides superior anatomic detail, sedation is commonly needed for the pediatric patient, impeding assessment of the patient’s mental status. Therefore, CT, which provides rapid imaging and is highly sensitive for the detection of acute blood and fractures, is often the initial imaging study of choice.

Neonatal Seizures

The common underlying causes of neonatal seizures differ from those in older children and adults (Box 174.2). In addition to congenital abnormalities, metabolic derangements, and birth-related injuries, neonatal seizures may be the only presenting sign of nonaccidental trauma. Diagnostic assessment of neonatal seizures is broad and includes metabolic testing (blood and urine), CSF analysis, and neuroimaging. Glucose, calcium, magnesium, and electrolyte levels (basic chemistry, including sodium, potassium, chloride, bicarbonate, blood urea nitrogen [BUN] and creatinine), and CBC should be obtained; lactic acid, ammonia, and pH determinations should be considered. Because clinical assessment for meningitis is not reliable in young infants, lumbar puncture should be performed and fluid sent for cell, protein, and

**Box 174.2**

**Common Causes of Neonatal Seizures**

- Hypoxic ischemic encephalopathy
- Central nervous system infection
- Intracranial hemorrhage
- Trauma (accidental and nonaccidental)
- Cerebral infarction
- Chromosomal or congenital brain abnormalities
- Inborn errors of metabolism or other metabolic derangements
- Drug withdrawal or intoxication
glucose determinations, culture, and herpes simplex PCR assay. Head CT or MRI should also be performed. In the unstable neonate, a head ultrasound may be performed at the bedside to evaluate for a neurosurgical emergency until more definitive imaging can be obtained.

Empirical antibiotic therapy should be started in infants with suspected meningitis (see previous section). Acyclovir (20 mg/kg/dose IV tid) is initiated if herpes encephalitis is a clinical concern—CSF pleocytosis, continued seizures with no other clear cause, or concerning maternal history; CSF red cells are a late and ominous finding.

Electrolyte abnormalities, including hypoglycemia, hypomagnesemia, and hyponatremia, should be promptly corrected. Hypoglycemia is treated with 2 mL/kg of 10% dextrose solution IV. Hypocalcemia is corrected with 10% calcium gluconate (1 mL/kg over 5 to 10 minutes, with monitoring of the heart rate and infusion site) or calcium chloride (0.2 mL/kg). Caution should be used when administering calcium chloride because it can be highly caustic to peripheral veins. Hypomagnesemia may be associated with hypocalcemia, is treated with a 0.25-mL/kg dose of 50% solution magnesium sulfate injected intramuscularly (to avoid arrhythmias associated with intravenous administration).

Phenobarbital is the usual drug of choice for neonatal seizures. A loading dose of 20 mg/kg should be given; additional doses of 5 mg/kg may be given every 15–30 minutes up to a maximum of 30 mg/kg, if needed. It may be necessary to support respirations with additional doses. If seizures continue, fosphenytoin, 20 PE/kg, may be loaded. Lorazepam, 0.1 mg/kg IV, may be useful but is associated with hypotension and respiratory depression. Refractory seizures may be treated with a midazolam infusion.18 At this point, continuous electroencephalographic recording should be instituted. If seizures are refractory to medical treatment, empirical treatment with pyridoxine, 100 mg IV, should be considered.

Disposition

Hospitalization is unnecessary for most patients after a first unprovoked seizure as long as the neurologic examination is normal and follow-up evaluation arranged. Electroencephalography and imaging studies can be performed on an outpatient basis. Children with simple febrile seizures can almost always be sent home. Guidance for families should include likelihood of recurrence, development of febrile seizure, fever control, and emergency measures for seizure. For the child who has had a prolonged febrile seizure or cluster of seizures, a prescription for rectal diazepam can be given for outpatient use after consultation with the child’s neurologist or primary care physician. Parents should give Diastat only if a seizure continues beyond 5 minutes.

Children who have had a prolonged seizure or who are not back to their baseline within a few hours should be admitted to the hospital. Hospitalization should also be considered if adequate follow-up evaluation cannot be arranged or in the case of extreme parental anxiety.

Neonates with seizures require admission and continuous cardiorespiratory monitoring.

Anticonvulsant Therapy at Discharge

The decision to start anticonvulsant prophylaxis should balance the risk for the recurrence of seizures against the potential complications associated with long-term medication use and should be done in consultation with a pediatric neurologist. Side effects of medications are common and include sedation, dizziness, blurred vision, ataxia, gastrointestinal disturbances, and cognitive and behavioral changes. Idiosyncratic reactions include hepatic toxicity, agranulocytosis, aplastic anemia, rash, Stevens-Johnson syndrome, and serum sickness.

Two-thirds of children with a first unprovoked seizure never experience a recurrence.19 The risk for recurrence is increased with the presence of neuroimaging or electroencephalographic abnormalities, developmental delay, family history of epilepsy, remote symptomatic seizure, first seizure occurring during sleep, or Todd’s paralysis. If none of these risk factors is present, the 5-year recurrence risk is only 21%. There is no evidence that early treatment with anticonvulsant medications after a single seizure alters the risk of epilepsy, nor is there evidence to show that a single self-limited seizure causes neurologic sequelae. In light of these considerations, anticonvulsants are generally started after a second unprovoked seizure.

Patients with acute symptomatic seizures associated with a risk factor for recurrence, such as cerebral hemorrhage, meningitis, or contusion, should be treated in the hospital with prophylactic anticonvulsants, such as phenytoin or fosphenytoin. The decision to continue treatment should be made once the patient is stable.

The choice of medication is dictated by the seizure type and syndrome and the side effect profile of the agent (Table 174.7). Drug levels should be monitored with many anticonvulsants. Of the older medications, phenytoin, phenobarbital, valproic acid, and carbamazepine are all excellent medications for the treatment of generalized or partial seizures. However, phenytoin is a poor long-term choice for children because of the development over time of hirsutism, gum hyperplasia, and facial coarsening. Phenobarbital is rarely used in children older than 2 years because of

HEADACHES

Principles

Headache is an extremely common problem in children and adolescents. Studies of schoolchildren have indicated that 40% of children will experience a headache by 7 years, and 75% by 15 years of age. Migraine, one of the most common causes of headache in childhood, with notable associated morbidity, has a prevalence of 8% to 23% by 15 years of age. Although most pediatric patients have benign causes of headaches, a thorough history and physical examination can evaluate for serious underlying pathology and decide if further studies, such as neuroimaging, are necessary.

Migraine headaches are multifactorial in cause, with environmental and genetic contributions likely. The principal mechanism of migraine headaches is thought to involve a primary dysfunction of the brain in which a wave of spreading cortical neuronal depression is accompanied by vascular changes. Derangement of the trigeminovascular reflex results in alterations of regional blood flow, and this neurovascular interaction is thought to contribute to neurogenic inflammation and the development of migraine headaches. Serotonin (5-hydroxytryptamine [5-HT]) may be a key mediator in this cascade of events. Serotonin agonists have been shown to relieve migraine pain.

Clinical Features

Headaches can be classified into five temporal patterns—acute, acute recurrent, chronic progressive, chronic nonprogressive, and mixed. An acute headache is new in onset and different from previous headaches; it can herald a broad range of conditions, ranging from a viral illness to subarachnoid hemorrhage. Acute recurrent headaches can be expressed as periodic events separated by pain-free intervals. Chronic progressive headaches occur over weeks to months. They can signify serious medical disorders, such as brain tumors or arteriovenous malformations. Chronic nonprogressive headaches usually occur for years and are classified as primary headaches (as opposed to secondary symptomatic headaches, which are caused by an underlying medical problem). Mixed headaches are acute recurrent headaches (migraine) superimposed on a pattern of daily chronic nonprogressive headaches.

The primary goal of the ED evaluation is to differentiate life-threatening causes of headaches from primary headaches, such as migraine or tension headaches. The child's history is the most important component to an accurate diagnosis. The patient and family members should be asked about specific factors related to the headache, such as time of onset, duration, location, laterality, quality (sharp, dull, throbbing, aching), relieving and exacerbating factors, precipitating factors (poor sleep, hunger, specific foods), and associated symptoms, such as nausea, vomiting, or phonophobia.

In addition to the important questions in Table 174.8, the emergency clinician should focus on a detailed history of the neurologic system to identify any related symptoms (eg, vomiting, lethargy, ataxia, seizures, weakness, visual disturbances) and a general review of other organ systems. Warning signs of secondary headaches include sudden onset, occurrence with straining or exertion, association with neurologic symptoms, change in headache pattern, nocturnal awakening, and bilateral occipital headaches. Additional information related to the past medical history (eg, history of recent head trauma, neurologic or psychiatric disorders, hospital admissions, medications) should also be obtained.

The physical examination should begin with vital signs. Height, weight, and head circumference should be compared with standard percentiles and the child’s previous growth history; a change in the rate or direction of head growth may indicate an intracerebral mass or hydrocephalus. The blood pressure should be carefully measured, with the use of age-appropriate cuff size and percentiles for age; hypertension may be a sign of increased ICP. An infant’s fontanelle should be auscultated for bruits associated with arteriovenous malformations, and a skin examination should be performed to look for stigmata of neurocutaneous disorders, such as neurofibromatosis (cafe-au-lait spots; Fig. 174.2) or tuberous sclerosis (ash leaf spots; Fig. 174.3). The neurologic examination should begin with assessment of the child’s mental status and overall development. For infants, observing their level of alertness, age-appropriate social interaction, overall tone, and general vigor is an essential component of the initial neurologic evaluation. Nonspecific findings such as irritability, fussiness, or poor feeding may be the only presenting signs in infants with headache. The neurologic examination should include a complete assessment of cranial nerves, gait analysis, cerebellar, sensory, and motor function testing, and evaluation of deep tendon reflexes. The ophthalmologic examination should

Although far less common, arteriovenous malformations can be a trigger for a new severe headache. Intracranial arteriovenous malformations are structurally unstable and thus susceptible to spontaneous rupture. In children, the abrupt onset of a severe headache in the absence of trauma (especially when accompanied by focal neurologic findings) suggests an acute intracranial bleed, and a head CT should be performed after stabilization of the airway, breathing, and circulation. Localized acute headaches without focal neurologic findings commonly are due to sinusitis, otitis media, dental disorders, or traumatic head injury. Headache associated with trauma should be carefully investigated for the possibility of subdural or epidural hematomas, fractures, and leptomeningeal cyst (a “growing” skull fracture, usually in a child <3 years of age, with a history of recent trauma). Ophthalmologic problems, such as astigmatism, refractory errors, eye strain, and squint, are occasionally responsible for headaches in children.

**Chronic Progressive Headache.** Chronic progressive headaches in children often signify underlying pathology that is evolving to cause increasingly severe headaches over time. The development of increased ICP can be caused by brain tumors, pseudotumor cerebri, hydrocephalus, brain abscess, or intracranial bleeding. Headache that awakens the child from sleep, is present on first awakening, or is associated with morning emesis is a classic symptom of increased ICP and is often due to an intracranial mass or hydrocephalus. In the setting of an abnormal intracranial entity, such as a mass or CSF obstruction, impaired venous outflow in the supine position leads to excess volume inside the skull, generating elevated pressure. The physical examination may show signs of increased ICP—vital sign changes, including hypertension, bradycardia, and irregular respirations; papilledema; brisk reflexes; cranial nerve deficits; positive Babinski sign; and decreased level of consciousness—as well as focal symptoms related to the location of the lesion (eg, hemiparesis, ataxia, visual field deficits).

Headaches are more likely to be the first symptom of a brain tumor in older children. Frequently, there are associated symptoms, such as nausea, vomiting, visual effects, problems with walking, weakness, loss of developmental milestones, changes in personality or school performance, and/or speech changes. Often, the diagnosis of a brain tumor is made after one or more clinical visits for headache as the symptoms progress and evolve. Neurologic findings in children newly diagnosed with brain tumors may include papilledema, abnormal eye movements, ataxia, abnormal tendon reflexes, and abnormalities on the visual examination. Clinical findings of pseudotumor cerebri (idiopathic intracranial hypertension or benign intracranial hypertension) are secondary to the increased ICP and include papilledema, sixth cranial nerve palsy, and visual field obstruction. Pseudotumor cerebri is more common in females and obese individuals. In younger children it is associated with medications (eg, vitamin A, steroids, birth control pills, tetracycline), and obstruction of the major venous sinuses. By definition, neuroimaging findings are normal. The LP usually demonstrates elevated pressure, often higher than 20 cm H$_2$O, and normal CSF protein and glucose levels. Neuroimaging should precede LP when increased ICP is suspected from mass or injury. Treatment can include repeat LP alone or with diuretics and LP for therapeutic removal of CSF. Hydrocephalus may be related to a previous episode of meningitis, subarachnoid hemorrhage, or head injury or may be congenital.

Brain abscess can result from meningitis, head trauma, chronic otitis media and sinusitis, or septic embolization in children with congenital heart disease. Focal neurologic signs, as well as fever and headache, may be present, but the patient may look surprisingly well. CT of the head without contrast enhancement is not sufficiently sensitive when an abscess is considered.

**Diagnostic Considerations**

### Differential Diagnoses

Headaches may be primary (migraines, cluster headaches) or secondary to an underlying disease process. The list of differential considerations for secondary headaches is extensive and should be considered in the context of the child’s history and physical examination (see Table 174.7).

**Acute Headache.** The acute headache is a common problem in children and adolescents and accompanies many infectious processes. In the absence of other signs of CNS involvement (eg, nuchal rigidity, alteration in level of consciousness, focal neurologic findings), headaches in febrile children usually do not constitute evidence of CNS infection. Non-specific viral illnesses represent most diagnoses in children presenting to the ED with an acute headache.
in the differential but may be obtained; CT with and without contrast enhancement or MRI should be performed. CSF findings (performed only after neuroimaging) usually include a mild leukocytosis (10–200 leukocytes/mm³), slightly elevated protein level, and normal glucose level. The CSF smear and culture usually do not reveal any organisms.

A subdural or epidural hematoma is associated with head trauma. Headaches in these patients may evolve and progress over a relatively short time period. Symptoms include those associated with increased ICP, seizures, and focal neurologic deficits. The diagnosis is confirmed by neuroimaging.

Chronic progressive headache also can be a symptom of systemic diseases, such as hypertension, collagen vascular disease, hypothyroidism, Lyme disease, mononucleosis, or inborn errors of metabolism.

**Migraine Headache.** The diagnosis of migraine is based on symptoms of recurrent headaches separated by pain-free intervals. A revised classification of migraine syndromes has been developed for pediatric migraines. Pediatric migraines may last 2 to 72 hours and are more often bilateral compared to unilateral, which is more common in adults. Photophobia and phonophobia may be more difficult to assess in the young child or infant. Occipital headaches are rare and should raise clinical suspicion for an underlying diagnosis other than migraine.

Migraine headaches are classified primarily into migraine with and without an aura. Migraine without an aura, also known as common migraine, is the most frequent type of pediatric and adolescent migraine and includes the following criteria—more than five attacks that last 2 to 72 hours (untreated or unsuccessfully treated), accompanied by nausea, vomiting, photophobia or phonophobia—and including a minimum of two of the following criteria—unilateral or bilateral location, pulsing quality, moderate to severe intensity, and aggravated by routine physical activities.

Migraine with an aura, previously known as classic migraine, is diagnosed when at least two attacks fulfilling the diagnosis of migraine occur accompanied by a variety of sensory warning symptoms, such as flickering lights, loss of vision, and tingling or numbness. The aura typically develops over 5 or more minutes and completely resolve within 60 minutes.

Migraine variants or atypical migraines are more common in children. Hemiplegic migraine is characterized by the sudden onset of hemiparesis or hemiplegia, along with headache in the contralateral hemisphere. Even though symptoms usually last for hours or even days, patients are rarely left with permanent deficits. Ophthalmoplegic migraine is characterized by severe unilateral eye pain and headache, followed by ipsilateral third nerve palsies of variable degrees. Rarely, the fourth or sixth cranial nerve, rather than the third nerve, may be affected. Basilar artery migraine, also common in children, is manifested with a combination of visual symptoms (eg, transient bilateral blindness, blurred vision) and visual hallucinations, vertigo, ataxia, loss of consciousness, and drop attacks. An acute confusional state can be associated with migraines and is characterized by changes in personality, orientation, or behavior. The so-called Alice in Wonderland syndrome includes perceptions of distortion in body images and shapes; objects appear much larger (macropsia) or smaller (micropsia) before, during, or after the headache.

Migraine variants are not uncommon and can be misdiagnosed. Abdominal migraine is characterized by recurrent abdominal pain, nausea, vomiting, and recurrent headaches. Benign paroxysmal vertigo of childhood (distinct from benign paroxysmal positional vertigo) is manifested as headache accompanied by the sudden onset of vertigo, pallor, and nystagmus. Paroxysmal torticollis is defined as recurrent episodes of head tilt associated with headache, nausea, and vomiting. Of note, this is a diagnosis of exclusion; a child with a head tilt, vomiting, and headache should first be evaluated for a posterior fossa lesion. Ocular migraine is characterized by transient monocular visual blurring to blindness with bright flashes of light.

The incidence of seizures is higher in patients with migraine than in the general population. Although epilepsy and migraine headache are distinct clinical syndromes, they share several characteristics, such as aura, vertigo, nausea, pallor, loss of consciousness, drowsy postictal state, confusion, and transient focal neurologic deficits. Headache as the sole manifestation of a seizure is uncommon; however, headaches frequently follow tonic, tonic-clonic, and brief complex partial seizures. Bilateral frontal throbbing headaches may follow episodes of status epilepticus. Further neurologic evaluation, including electroencephalography, may occasionally be necessary to distinguish between these two syndromes.

**Chronic Nonprogressive Headache.** Chronic nonprogressive headache is commonly seen in the adolescent population. Included in this category are muscle contraction and conversion headaches. The International Headache Society classification of headaches refers to these types of headaches as tension headaches.

This type of headache includes the following symptoms: bilateral or unilateral, nonthrobbing, pressing, or bandlike tightness of mild to moderate intensity, and the absence of nausea, vomiting, and aura. Tension headaches are further classified as episodic (10–15 episodes/month lasting 30 minutes to 7 days) or chronic (>15 episodes/month for more than 6 months).

**Cluster Headache.** Cluster headache is a distinctive headache syndrome that is more common in males and rare in those younger than 10 years. Cluster headache is characterized by one to several attacks recurring each 24 hours, during several weeks to months. Headache-free periods between clusters may last months to years. The pain is throbbing, severe, and unilateral; occurs over the same orbitotemporal region, and is associated with ipsilateral scleral injection, lacrimation, nasal stuffiness, and sometimes a partial Horner’s syndrome (enophthalmos, ptosis, miosis, and anhidrosis, unilateral, affecting sympathetic innervation of the eye). The pain lasts 30 minutes to several hours and can occur at any time of day or night.

**Diagnosis Testing**

Although most patients presenting to the ED do not require neuroimaging or laboratory evaluation if neuroimaging is obtained, MRI provides superior anatomic detail compared with CT and is particularly useful in the detection of abnormalities in the sella turcica, posterior fossa, and cervicomедullary junction. MRI is also better for detecting arteriovenous malformations and low-grade tumors. CT scanning, however, is superior to MRI for the detection of acute blood and skull fractures and therefore is often the modality of choice in the ED if neuroimaging is emergently required. Indications for the use of neuroimaging are presented in Box 174.3.

An LP is indicated for the diagnosis of an infectious process, subarachnoid hemorrhage not detected by CT, or idiopathic intracranial hypertension. If a mass lesion is suspected (eg, early-morning headaches and vomiting, progressively worsening headaches, or focal neurologic findings), radiologic imaging should precede an LP.

Chronic progressive headaches may be a symptom of a systemic disease. Guided by the history and physical examination, laboratory tests may include CBC, urinalysis, erythrocyte sedimentation rate, antinuclear antibody testing, liver function studies, thyroid function studies, serum lipid assay, serum magnesium, lactate, and pyruvate concentrations, and Lyme disease titers.
**Indications for Radiologic Imaging in Patients With Headache**

**STRONGLY INDICATED IF:**
- Abnormal neurologic examination findings
- Signs and symptoms of elevated intracranial pressure
- Meningeal signs plus focal neurologic findings or altered mental status
- Progressive or new focal neurologic signs
- Significant head trauma
- Severe nocturnal headaches that awaken the patient from sleep or are present on awakening
- Severe (characterized by patient as "worst headache of my life") headaches; new or of increasing frequency and duration
- Presence of ventriculoperitoneal shunt
- Chronic progressive headache

**CONSIDER IF:**
- Headache or vomiting on awakening
- Unvarying location of headache, especially occipital
- Persistent headache plus no family history of migraine
- Neurocutaneous syndrome
- Age < 3 years (limited verbal skills)

**Management**

Treatment of primary childhood headaches requires attention to initial pharmacologic management as well as reassurance, removal of potential triggers, and initiation of a behavioral management program. The most important aspect of management is a thorough history and physical examination, past medical history of migraines or systemic disease, and targeted diagnostic evaluation for potentially life-threatening causes.

In addition to the use of standard oral analgesics, selective abortive treatment for children with migraine headaches has been recommended. There is little evidence to support precise medication regimens but, for the initial management of children with severe migraines presenting to the ED, management generally involves IV fluid hydration with a normal saline bolus, nonopioid analgesic such as IV ketorolac, and antiemetic such as prochlorperazine.

**Disposition**

Children with primary headaches are not hospitalized for care unless the diagnosis is uncertain and a serious cause of secondary headache is being considered. On discharge from the ED, patients may be given a variety of treatment recommendations (discussed below) while stressing the importance of close follow-up with a primary care provider for ongoing management of migraines.

Nonmedical interventions may have some impact and should be strongly considered. These include avoidance of triggers, placement of the child in a darkened room, with minimal or no extraneous noise, avoidance of hypoglycemia by feeding during a migraine, avoidance of caffeinated beverages (except for possible use as a migraine medication during an episode), application of a cool compress on the forehead, use of a gentle fan, and breathing exercises and relaxation techniques. A headache diary can help identify potential triggers and effects of medications. Common triggers include reduction in sleep, perimenstrual stress, missed meals, and certain foods (eg, chocolate, processed meats, alcohol, hard cheeses, red wine, monosodium glutamate, yeast extracts, nuts, figs, aspartame, sauerkraut).

In general, there are several outpatient treatment options available for acute migraine headaches in children. For many patients, symptom relief can be achieved by oral analgesics such as acetaminophen or ibuprofen, along with rest and avoidance of triggers. In other cases, additional agents are needed, such as vasoconstrictors, sedatives, triptans, and antiemetics. Some children may respond well to small doses of caffeine.

Vasoconstrictor drugs are used less commonly in the pediatric than in the adult population. Antiemetic agents are often given include and include dopamine receptor antagonists such as metoclopramide, promethazine, and prochlorperazine as well as the serotonin receptor antagonist ondansetron. Sumatriptan, a selective 5-HT1 receptor agonist that can mediate cerebral vasocostriction and block inflammatory response, may also be used in this setting, although a review of medication trials of triptans in children with migraine highlighted the important finding that randomized clinical trials found no difference in outcome between the control and experimental groups. Sumatriptan can be administered orally, intranasally, or subcutaneously.

Combination medications, such as Fiorinal (butalbital, aspirin, and caffeine), Fioricet (butalbital, acetaminophen, and caffeine), and Midrin (isometheptene, acetaminophen, and dichlorphenazone) may be effective but should not be first-line treatment. In addition to producing an analgesic effect, these medications may produce alterations of emotional state, sedation, and psychological dependence.

The use of pharmacologic agents for prophylaxis in children with migraine headache requires careful observation and follow-up evaluation by the child’s primary care physician or a neurologist. Although controlled studies are extremely limited, current indications for these medications include more than two or three headaches per week and interference with lifestyle, particularly missed school days or inability to participate in social activities. In keeping with or perhaps reflecting the high spontaneous remission rate of childhood migraine, the placebo effect of many medications is high. Steroids may have a role in preventing recurrence after an ED visit for migraine. Medications that have been used include propranolol, amitriptyline, calcium channel blockers, anticonvulsants (particularly valproic acid), cyproheptadine, and naproxen sodium. Cyproheptadine, valproic acid, and naproxen are available in liquid form. Amitriptyline may be useful for adolescents with a diagnosis of migraine and muscle contraction headaches and for depressed children with headaches.

**DISORDERS OF BALANCE**

**PEDIATRIC ATAXIA**

**Principles**

Ataxia comes from the Greek word *ataktos*, meaning “lacking order,” and describes a pathologic abnormality of organization or modulation of movement. Congenital ataxia is associated with CNS abnormalities. Acquired ataxia can be acute, episodic, or chronic. The chronic ataxias are usually caused by inherited metabolic or genetic disorders. Usually, ataxia is caused by cerebellar dysfunction, but lesions in the corticospinal tract or dorsal columns of the spinal cord may also be causative.

**Clinical Features**

Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or sudden development of a wide-based so-called drunken gait. The history should identify any recent infection, injury, inadvertent drug ingestion, or other family members with similar symptoms. Mental status is usually normal in cases of

Postinfectious ataxia: if abnormal, the possibility of ingestion, acute disseminated encephalomyelitis, or stroke should be considered. Nystagmus is common if the cerebellum is affected. Papilledema or cranial nerve palsies suggest hydrocephalus or a CNS lesion.

### Differential Considerations

#### Diagnostic Considerations

In children, 40% of ataxia cases are caused by acute cerebellar ataxia. Box 174.4 delineates common causes of pediatric ataxia. Boys are more commonly affected, with the highest incidence at the ages of 2 to 4 years. A history of recent illness with multiple causative agents is seen in 70% of patients, but varicella virus is the most common, associated with up to 26% of cases. The disease is thought to be due to an autoimmune phenomenon leading to cerebellar demyelination. Symptoms and signs are maximal at the onset, with the extremities more seriously affected than the trunk, and range from unsteadiness and wide-based gait to complete inability to walk. Mental status is normal, and nystagmus is common. Fever and seizures are uncommon outcomes.

Acute postinfectious demyelinating encephalomyelitis can also cause ataxia and occurs in the recovery phase of a viral illness or vaccination. It is distinguished from acute cerebellar ataxia by alteration in consciousness and multifocal neurologic deficits, as well as by fever and frequent occurrence of seizures. Brainstem encephalitis can involve the cerebellum, causing ataxia in association with focal neurologic abnormalities and respiratory irregularities. Causative agents include Epstein-Barr virus, Listeria monocytogenes, and enteroviruses.

Up to 32% of cases of acute childhood ataxia are due to drug toxicity, usually anticonvulsants, benzodiazepines, alcohol, or antihistamines or, less commonly, from exposure to organic chemicals or heavy metals. The ataxia is usually accompanied by lethargy, confusion, and inappropriate speech or behavior. Nystagmus may be present.

Approximately 45% to 60% of all childhood brain tumors arise in the brainstem or cerebellum and can be manifested with slowly progressive ataxia. Acute decompensation can occur, with the development of hydrocephalus or hemorrhage into the lesion.

Head injuries with cerebellar contusion or hemorrhage can cause ataxia. Posterior circulation strokes are rare in children but should be considered after neck trauma, with possible vertebral artery dissection as a cause of the ataxia.

The opsoclonus-myoclonus syndrome consists of ataxia, rapid, chaotic, multidirectional eye movements, and myoclonic jerks of the extremities, head, trunk, and face. This is usually a presenting manifestation of neuroblastoma or ganglioneuroblastoma, in which the ataxia is thought to be due to a paraneoplastic autoimmune phenomenon involving cross-reactivity of tumor and cerebellar antigens. Spontaneous vertebral artery dissections also have been reported in children.

Ataxia can be seen in patients with basilar migraine and can be associated with vertigo, hemiparesis, cranial nerve dysfunction, nausea, vomiting, and/or headache. Loss of sensory input to the cerebellum can cause a sensory ataxia. Clinical manifestations include a Romberg sign, decreased deep tendon reflexes, and impaired proprioception and vibration sense. Of patients with Guillain-Barré syndrome (GBS), 15% have sensory ataxia. In the Miller Fisher variant of GBS, the triad of ataxia, areflexia, and ophthalmoplegia of vertical gaze is characteristic.

Transient ataxia can be present in the ictal or postictal phase of seizures. Repeated attacks of ataxia can be the presenting manifestation of multiple sclerosis. Inborn errors of metabolism can also manifest with ataxia, acutely or intermittently, depending on dietary intake or the presence of other illness. Inborn errors of metabolism should be considered when ataxia is accompanied by lethargy, encephalopathy, vomiting, diarrhea, loss of muscle tone, or unusual body odor, as in urea cycle defects (aminoacidurias) or defects in pyruvate and lactate metabolism. Ataxia is associated with other inherited diseases such as Niemann-Pick, Tay-Sachs, and Wilson’s diseases.

The two most common genetic disorders associated with ataxia are Friedreich’s ataxia and ataxia-telangiectasia. Friedreich’s ataxia is a disorder of autosomal recessive inheritance characterized by progressive gait and limb disturbance. Affected patients demonstrate dysarthria, lower limb areflexia, proprioceptive sensory loss, and high-arched feet (pes cavus). Ataxia-telangiectasia is a disorder of recessive inheritance manifested as a truncal ataxia in infancy that leaves most patients wheelchair-bound by the age of 12 years. Oculocutaneous telangiectasias usually appear by the age of 3 to 5 years. These patients also demonstrate dysarthria, nystagmus, dystonic posturing, myoclonic jerks, and accelerated aging.

#### Diagnostic Testing

An accurate diagnosis for pediatric ataxia is dependent on a complete history and thorough physical examination, including testing of gait and cerebellar function. Urine and serum toxicology studies are the highest yield laboratory studies. CT and MRI findings are usually normal in patients with postinfectious ataxia, but demyelination, tumor, hydrocephalus, or traumatic injuries may be identified. CSF analysis may show mild pleocytosis or lymphocytosis in acute postinfectious ataxia; findings are normal in most other cases.

Electroencephalography is recommended for patients with altered consciousness and fluctuating clinical signs. A pattern of epileptiform discharges or slowing is seen in 66% of children with acute cerebellar ataxia. Electroencephalography can diagnose nonconvulsive or convulsive seizures. The electroencephalographic pattern is normal in the opsoclonus-myoclonus syndrome. Electromyography may be helpful if sensory ataxia is suspected and may help diagnose GBS, although this is less feasible in the ED setting. Urinary catecholamine levels can be assayed for diagnosis of neuroblastoma. Testing for inborn errors of metabolism includes a CBC, liver function tests, glucose, ammonia lactate, pyruvate,
and ketogenic levels, and determination of acid-base status. The four most high-yield tests are for levels of glucose, lactate, ketones, and ammonia. If all four of these are normal, it is unlikely that there is an inborn error. Any other laboratory tests should be ordered in consultation with a geneticist and may include plasma and urinary amino acid, urine organic acid, and CSF lactate assays and determination of the serum biotinidase level.

Management

Most children with acute postinfectious cerebellar ataxia recover completely, and treatment is supportive in nature. Improvement is seen within 1 week, and the vast majority recover completely within 2 to 4 weeks. Some children exhibit persistent gait disturbances, ataxia, and delayed speech development.

Disposition

Children with ataxia usually require hospital admission and consultation with a pediatric neurologist for patients in whom the cause of the ataxia is not evident on the ED evaluation.

PEDIATRIC VERTIGO

Principles

Vertigo, also discussed in Chapter 16, is defined as an illusion of movement, a sensation that the external world is revolving around an individual (objective vertigo) or that the affected person is revolving in space (subjective vertigo). Vertigo is well recognized to occur in the pediatric age group and has many potential causes. Disease processes that affect the balance of the vestibular, visual, and proprioceptive systems can cause vertigo by impairing the neural activity of the vestibular nucleus. Diseases of the ear, eighth cranial nerve, neck, brainstem, or eye can lead to vertiginous symptoms. Vertigo is characterized as central or peripheral, depending on whether the cause is in the CNS.

Clinical Features

Vertigo is often described as dizziness. There may be a history of sudden falls, grasping for support, or unwillingness to move. A review of systems should include those related to the ear, such as otalgia, hearing loss, and tinnitus. Other important historical features that should be determined include headache, loss of consciousness, head trauma or barotrauma, and family history of migraine or seizure disorders.

Diagnostic Considerations

Diagnostic Testing

Patients can be divided into those who have hearing loss and those who have normal hearing. In the group with hearing loss, further characterization of the loss as conductive or sensorineural (using the Weber and Rinne tests) can help localize the peripheral lesion from the middle ear, labyrinth, or eighth cranial nerve.

Differential Diagnoses

Although vertigo is not as common in the pediatric age group as in adults, it has many potential causes (Box 174.5). It usually is helpful to separate conditions that cause vertigo into those with and without associated hearing loss.

Benign paroxysmal vertigo of childhood is defined by the repeated occurrence of vertiginous episodes lasting seconds to minutes, with occasional vomiting. In addition to being pale and diaphoretic, preverbal children may appear fearful, grasping onto a caregiver’s leg for stability. This entity usually remits spontaneously within months to years. The most frequent cause of benign paroxysmal vertigo of childhood is a migraine headache, with vertigo occurring as the aura of an episode.

Patients with basilar artery migraines also present with vertigo, hemiparesis, ataxia, palsies of the third, sixth, or seventh cranial nerve, drop attacks, and blindness in various combinations, followed by migraine headache. Children with benign paroxysmal vertigo of childhood or basilar migraines usually have a family history of migraine headaches.

Benign paroxysmal positional vertigo is rare in children, but can occur spontaneously as well as after trauma. The earliest age at which it has been reported is 11 years. It is believed to be due to otoliths that have moved out of their normal positions in the utricle and is corrected by canalith repositioning maneuvers (eg, Epley maneuver).

Ménière’s disease, a syndrome with a combination of vertigo, fluctuating hearing loss, and tinnitus, is responsible for 1.5% to 4% of cases of pediatric vertigo. Vestibular neuritis, thought to be caused by viral infections, is manifested as vertigo without hearing loss. A preceding cold is found in 60% of patients. It is manifested with severe vertigo that resolves in a few days, after which the child

will have vertigo only with rapid head movements, which persists for weeks or months until central compensation occurs.

Labyrinthitis is an inflammatory process involving the inner ear membranous labyrinth; it manifests with vertigo, hearing loss, and tinnitus. Cytomegalovirus, rubella virus, and rubeola viruses are common causative agents. Bacterial labyrinthitis usually occurs in association with meningitis and should be suspected in any ill child with vertigo and high fevers, especially in combination with a perforated tympanic membrane. Neurofibromatosis can be manifested with vertigo if it involves the superior vestibular nerve. Other genetic syndromes such as Alport syndrome are also associated with vertigo (see Box 174.5).

Ototoxic drugs, such as aminoglycosides and chemotherapeutic agents, can cause vertigo, usually in association with hearing loss. Cerebellar and brainstem lesions can also cause with vertigo. Cranial nerve deficits associated with vertigo may indicate a brainstem lesion or tumor. Vertigo is the presenting symptom in 5% to 12% of cases of multiple sclerosis.

For most patients, the cause of vertigo cannot be made in the ED. A complete physical examination, including an otologic and neurologic evaluation, should be performed, including nystagmus and cerebellar testing. Having the child hop and stand from a seated position on the floor, with eyes open and closed, can reveal vestibular dysfunction. Signs of other disease processes, such as café au lait spots in neurofibromatosis, may aid in the diagnosis. Laboratory tests in the vertiginous patient should be dictated by the history and physical examination and may include glucose and electrolyte level assessment, thyroid function tests, and viral titers or serologic studies (eg, for Lyme disease or syphilis). CT or MRI is indicated for patients for whom an underlying CNS abnormality (central vertigo) is suspected.

Management

Management of the vertiginous patient depends on the underlying cause, which may not be evident in the ED. For acute symptomatic relief, vestibular suppressants such as meclizine and diazepam may be helpful.

Disposition

Patients with suspected CNS infection, focal neurologic deficits, abnormal mental status, or inability to ambulate or tolerate oral medication should be admitted. Patients should follow-up with a neurologist or otolaryngologist for follow-up testing.

MOTOR DYSFUNCTION

Acute weakness or motor abnormalities in the pediatric patient can result from pathology at a variety of levels in the neural axis. A complete neurologic assessment can indicate the location of pathology—upper motor neuron (motor neurons originating in the cerebral cortex or brainstem) or lower motor neuron (the spinal cord anterior horn cells, peripheral nerve, neuromuscular junction, and the muscle itself). Upper motor neuron pathology generally creates spasticity, increased tone, hyperreflexia and no fasciculations. Lower motor neuron abnormalities demonstrate decreased tone and reflexes, with fasciculations.

STROKE

Principles

Although less common in children than adults, pediatric strokes are important to recognize and treat promptly. Stroke is characterized by the acute onset of focal neurologic deficit lasting more than 24 hours. Underlying conditions that predispose children to stroke include sickle cell disease, structural cardiac anomalies, and moyamoya disease (Box 174.6). Because stroke mimickers (eg, migraines) are much more common than strokes in pediatric populations, the diagnostic evaluation may be erroneously delayed.

Strokes are classified as ischemic or hemorrhagic in nature. In ischemic stroke, there is an interruption of blood supply to a particular area of the brain, resulting in hypoxic injury. In hemorrhagic stroke, the rupture of a blood vessel or an abnormal vascular structure causes focal damage. Hemorrhagic strokes are more common in children than adults and often stem from unstable arteriovenous malformations.

Clinical Features

Manifestations of stroke in infants and children are widely variable due to the potential affected areas of the brain, as well as the child’s age and development. Common presenting features of stroke include hemiparesis and facial weakness. In addition to focal motor findings, children may also present with headache, seizures, or altered level of consciousness. The middle cerebral and anterior cerebral arteries are usually affected in children with stroke, generating upper extremity hemiplegia and lower extremity weakness, respectively. The posterior circulation, although less commonly involved, may produce ataxia, nystagmus, or vertigo, along with hemiparesis and hemianopsia.

Diagnostic Considerations: Diagnostic Testing

Imaging of the brain can confirm the diagnosis of stroke in infants and children. A noncontrast head CT scan can reveal the presence of a bleed, but may not show evidence of ischemia if the stroke took place in the preceding 24 hours. Early consultation with a pediatric neurologist or neurologist is prudent. Urgent MRI and MR angiography (MRA) are indicated if there is no evidence of hemorrhage on head CT and clinical suspicion for stroke remains high. If the child does not have a predisposing condition for stroke, additional laboratory evaluation may be helpful, including a CBC and coagulation studies, inflammatory markers, chemistry and lipid panels, and toxicology screen. Electrocardiography and echocardiography can reveal structural abnormalities associated with intracardiac clots.

Management

Initial pediatric stroke management is directed at stabilization of the airway, breathing, and circulation and controlling any seizure activity. To prevent secondary brain injury, hypoxemia and hypotension should be avoided. When present, hypertension should be managed with consideration of possible increased ICP, particularly in the setting of a hemorrhagic stroke. Blood pressure should be slowly reduced while maintaining cerebral perfusion pressure. The metabolic demands of the brain should be minimized by controlling fevers, pain, and agitation. Any hyperglycemia or hypoglycemia should be corrected, particularly in the setting of an ischemic stroke.

Additional therapy and definitive treatment of stroke in children are ultimately dictated by the type and extent of the stroke. In the case of hemorrhagic stroke, neurosurgical intervention is often required for intracranial decompression, blood evacuation, or control of active bleeding. For children with sickle cell disease, an urgent blood transfusion should be considered to decrease the circulating level of hemoglobin S. Although well studied and implemented in adults, thrombolytic therapy for stroke in children has not been well examined. Thrombolytics, however, have increasingly been used for children with ischemic stroke. We recommend rapid transfer to a pediatric stroke center, when feasible.
Clinical Features

Regardless of the cause of acute spinal cord dysfunction, patients will present with certain characteristic findings, including paraplegia, hyporeflexia, and sensory deficits (complete sensory loss or paresthesias) below the level of the spinal cord lesion(s). Also, if the distal portion of the cord is affected, patients will have bowel and bladder incontinence. In the case of transverse myelitis, the thoracic region is usually affected. Children may demonstrate lower extremity paresthesias or pain with progressive weakness, which may be asymmetric, over a period of hours to days, and possibly urinary retention. There is often a history of a recent viral-like illness. An acute onset of local back pain with neurologic deficits suggests spinal cord compression due to a bleed, trauma, or infection. With infectious causes, pain may be the first sign, before fever, neurologic deficits, or other systemic signs. With oncologic processes such as spinal tumors, children may have a more insidious onset of symptoms and have evidence of spinal cord compression in the absence of pain.

Diagnostic Considerations: Diagnostic Testing

Diagnosing children with acute spinal cord compression requires a high level of clinical suspicion based on history and physical examination. A careful neurologic examination should include...
strength, deep tendon reflexes, sensation, and evaluation of anal sphincter tone. In suspected spinal cord compression, priority should be on emergent neuroimaging with MRI of the spine while immobilizing the patient. CT is less helpful, and plain spine radiographs are of little value. An LP should not be performed when spinal cord compression is suspected. LP can be helpful in evaluating transverse myelitis, but should be performed only after confirmed by MRI.26,27

Management and Disposition

Initial management steps for the patient with spinal cord trauma include immobilization of the spine and immediate neurosurgical consultation. Steroids are no longer routinely recommended for spinal cord trauma. Children with an epidural abscess identified on MRI should be promptly treated with IV antibiotics and neurosurgical consultation for decompression or drainage. Antibiotic coverage should be tailored to match local bacterial resistance patterns. Generally, antistaphylococcal coverage, including methicillin-resistant *Staphylococcus aureus* (MRSA), is recommended. Patient-specific conditions such as recent surgery may warrant additional coverage. Administration of corticosteroids for epidural abscesses is controversial because evidence is lacking for routine use. Corticosteroids should be administered only in select cases and in conjunction with neurosurgical consultation.

*S. aureus* is the most common pathogen associated with epidural abscesses; thus, initial IV antibiotic therapy in the ED should include vancomycin to cover MRSA (in addition to methicillin-sensitive *S. aureus* [MSSA]) and coverage of gram-negative bacilli with a third- or fourth-generation cephalosporin, such as ceftazidime or cefepime. Consideration of additional anaerobic coverage is warranted for higher risk individuals (eg, associated sinus disease).

Surgical drainage in conjunction with IV antibiotic therapy is the mainstay of treatment of epidural abscesses. For spinal masses, surgical intervention is needed to decompress the cord and further elucidate the diagnosis. Supportive care is the underpinning of treatment for transverse myelitis; these children should be hospitalized for observation, IV corticosteroid therapy, and consideration of additional immunotherapy.26 Initiation of IV corticosteroid therapy in the ED and its specific dosing for children with transverse myelitis should be discussed with a neurologist. Although there are no randomized controlled trials to demonstrate the efficacy of IV corticosteroids in transverse myelitis, consensus favors their use; timing and optimal initial dosage should be determined in consultation with a neurologist.

**GUILLAIN-BARRÉ SYNDROME**

**Principles**

GBS is an acute, demyelinating polyneuropathy that typically presents as transient, symmetric, ascending paralysis in the setting of a recent infection. It is thought to be autoimmune-mediated and classically causes demyelination of motor and sensory nerves.

Children of all ages may be affected; however, it is uncommon in young toddlers and infants. Often, there is a history of a preceding minor viral or gastrointestinal illness in the weeks prior to presentation. *Campylobacter jejuni* is the most common infectious agent associated with GBS.28 The differential diagnosis for GBS is broad; a careful history and detailed neurologic examination will help localize the pathology to the peripheral nerves rather than to the brainstem, brain, spinal cord, neuromuscular junction, or muscle itself.29 The relatively acute and typically symmetric nature of GBS paralysis helps distinguish this diagnosis.

The primary mechanism of GBS is an immune-mediated attack on the myelin of peripheral nerves. It typically occurs in an ascending pattern and affects distal limbs initially. The process is thought to be mediated by an antecedent infection triggering an immune response, which, in turn, provokes the acute peripheral nerve demyelination.

**Clinical Features**

Lower extremity pain, paresthesias, and weakness in any combination may be the initial presenting symptoms of GBS, followed by progressive ascending weakness of the lower extremities.28 The weakness may progress rapidly over hours to involve the trunk and, importantly, the muscles of respiration. Deep tendon reflexes are typically diminished or absent at the time of presentation. Cranial nerve abnormalities may also be present; in the Miller-Fisher variant of GBS, they represent the main findings, with oculomotor palsies, ataxia, and areflexia in the absence of extremity weakness.

**Diagnostic Considerations: Diagnostic Testing**

The diagnosis of GBS is largely clinical; however, a lumbar puncture can be helpful. CSF typically reveals an elevated protein level, with normal glucose and protein levels and white blood cell count, known as albumin cytologic dissociation.

Management and Disposition

Given the potential risk of respiratory compromise or failure associated with progressive demyelination and weakness, patients with GBS should be admitted to the hospital for monitoring and supportive care. Bedside respiratory evaluations, such as forced vital capacity and negative inspiratory force, may be very useful in predicting respiratory compromise. Treatment with plasma exchange and IV immunoglobulin may be used in severe cases.28

**INFANT BOTULISM**

**Principles**

Infant botulism typically affects infants younger than 6 to 8 months. It results from intestinal colonization with *Clostridium botulinum*. A neurotoxin produced by *C. botulinum* impairs acetylcholine release from the presynaptic membrane, thereby affecting skeletal muscle, smooth muscle, and autonomic function. Infants develop constipation and poor feeding, with subsequent hypotonia and weakness (Fig. 174.4), which may require respiratory support.28 Most US cases of infant botulism are thought to arise from ingestion of environmental dust particles containing *C. botulinum* spores and may be associated with active construction areas in which there is disruption of the ground. Honey is also a potential reservoir for *C. botulinum* spores.

**Clinical Features**

Infant botulism typically has an insidious onset of symptoms, commonly starting with constipation. Over time, infants develop poor feeding, lethargy, hypotonia, and weakness. On examination, infants may have decreased deep tendon reflexes, cranial nerve findings such as poor suck and gag, weak pupillary reflexes, and/or ptosis.

**Diagnostic Considerations: Diagnostic Testing**

The diagnosis of botulism may be confirmed through isolation of botulinum toxin in the stool; however, this process may be delayed because infants are often constipated and laboratory processing times may be hours to days. As such, treatment should be initiated
**MYASTHENIA GRAVIS**

**Principles**

Myasthenia gravis is an autoimmune disorder characterized by autoantibodies directed against the acetylcholine receptor of the neuromuscular junction. This action produces intermittent and fatigable weakness. Myasthenia gravis is usually seen in adults; however, there are three types that affect children—neonatal (transient), congenital, and juvenile. The juvenile form of myasthenia gravis presents similarly to the adult form and will be discussed here. Children with juvenile myasthenia gravis are more commonly female and of early school age.

**Clinical Features**

Patients typically have waxing and waning weakness of the skeletal and facial muscles, exacerbated by repetitive use of these muscles. Facial weakness with bilateral ptosis that fatigues throughout the day is a common initial presenting sign. Oculomotor, truncal, and extremity weakness may also be seen.

**Diagnostic Considerations: Diagnostic Testing**

A history of fatigable weakness with predominantly facial muscle findings should raise a high clinical suspicion for myasthenia gravis. The Tensilon test may be used in the ED to confirm the diagnosis. Edrophonium (Tensilon), an acetylcholinesterase inhibitor, is administered IV. By blocking the action of acetylcholinesterase at the neuromuscular junction, the presence of acetylcholine is prolonged, and muscle weakness transiently improves. Atropine should be available during the administration of edrophonium to treat possible cholinergic reactions (eg, bradycardia).

**Management and Disposition**

Myasthenia gravis may be life-threatening. Ventilatory support should be provided in the event of marked truncal weakness and respiratory compromise or failure, particularly in the setting of an intercurrent illness, which can exacerbate myasthenia gravis symptoms. In patients without risk of respiratory failure, treatment can often occur on an outpatient basis, with close symptom monitoring and oral cholinesterase inhibitor therapy.

**KEY CONCEPTS**

- Causes of altered mental status in children include vascular events (eg, stroke, arteriovenous malformation with bleed), infection (eg, meningitis, sepsis, encephalitis), trauma, toxic ingestion, anatomic or structural abnormality (eg, intracranial mass or tumor), metabolic derangements, intussusception, or seizures, which may be subclinical.
- Altered mental status in children has a varied spectrum of clinical presentations, and may include any of the following: altered level of consciousness, excessive sleepiness, irritability, lethargy, and abnormal behavior.
- Signs and symptoms of bacterial meningitis vary by age and can include nonspecific manifestations in infants and young children, such as irritability and lethargy.
- Antibiotic therapy for the patient with suspected bacterial meningitis, should not be delayed by an LP. Initial antibiotic coverage should be broad and guided by the most likely pathogens in the patient’s age group.
- A careful and detailed history is instrumental in determining whether an event was a seizure. If the event was a seizure, the history should delineate which type of seizure occurred (partial or generalized) and whether the clinical event fits into a known epilepsy syndrome.
- Status epilepticus constitutes a neurologic emergency that carries high morbidity and mortality rates. Initial treatment is typically with IV lorazepam, followed by fosphenytoint.
- A simple febrile seizure is generalized, lasts less than 15 minutes, and occurs in a neurologically and developmentally normal child between 6 months and 6 years of age.
- Children with simple febrile seizures do not require blood and urine testing, other than as needed for the evaluation of fever source. In immunized infants 6 to 18 months of age with a first-time simple febrile seizure, a lumbar puncture (LP) can be avoided if the child is not-ill appearing, has returned to baseline, and there are no clinical signs of meningitis.
- The possibility of provoked seizures should be considered because many causes are treatable.
- Breath-holding spells occurs in children 6 months to 6 years of age, and are triggered by pain or emotional upset. After a trigger, the
child becomes pale or cyanotic and may lose consciousness, sometimes with a brief period of clonic movements or opisthotonos.

- Most headaches in children have benign causes that usually can be diagnosed by a careful history and physical examination. Radiologic evaluation by CT, MRI, or both may be necessary to rule out secondary causes of headache such as intracranial hemorrhage, subarachnoid hemorrhage, brain tumor, or brain abscess.
- Warning signs of secondary headaches include sudden onset, occurrence with straining or exertion, association with neurologic symptoms, change in headache pattern, nocturnal awakening, and bilateral occipital headaches.
- In children, 40% of ataxia cases are caused by acute cerebellar ataxia.
- A toxicology screen is the test with the highest diagnostic yield for acute-onset ataxia in children.
- Approximately 45% to 60% of all childhood brain tumors arise in the brainstem or cerebellum and can be manifested with slowly progressive ataxia.
- The cause of vertigo with hearing loss is significantly different from that of vertigo with no hearing loss. This differentiation can be helpful in guiding the diagnostic evaluation.
- When assessing an infant or child with motor weakness, it is important to distinguish presentations consistent with upper motor neuron pathology from lower motor neuron processes.

- Strokes are less common in children than in adults. They represent a neurologic emergency and may be hemorrhagic or ischemic in nature. Imaging with CT and/or MR can help confirm the diagnosis of stroke. An important component of stroke management involves the prevention of secondary brain injury.
- Spinal cord compression is a medical emergency regardless of cause and requires prompt diagnosis and treatment. It may arise from trauma, infection and inflammation, or malignancy.
- The diagnosis of Guillain-Barré syndrome (GBS) is largely clinical, although LP may be helpful in confirming the diagnosis. Patients with GBS are at risk for respiratory compromise and should be admitted to the hospital for observation and supportive care.
- The diagnosis of infant botulism is largely clinical. If there is high clinical suspicion, treatment should be initiated promptly, without awaiting laboratory confirmation. Given the risk of respiratory compromise, infants with botulism should be admitted to the hospital for observation and supportive care.
- Diagnosis of myasthenia gravis in the ED may be confirmed with the Tensilon test. The disorder can often be treated on an outpatient basis, but patients with truncal involvement and concern for respiratory compromise should be admitted to the hospital for observation and supportive care.

2200.e2

PART V Special Populations | SECTION ONE The Pediatric Patient

D. Methohexital
E. Propofol infusion

Answer: A. If the airway cannot otherwise be maintained, there is respiratory failure, or there is evidence of increased intracranial pressure, the patient should be intubated. Do not paralyze the patient unless absolutely necessary. If needed, consider short-acting neuromuscular blockers such as succinylcholine and vecuronium. The three most commonly used agents to treat convulsive status epilepticus are benzodiazepines, fosphenytoin, phenytoin, and barbiturates. Methohexital actually lowers the seizure threshold. Propofol infusions should be used with great caution in children.

174.5. A 3-year-old boy is seen for seizure-like activity at home. He has no prior history of epilepsy and no family history of seizures. His fever has been as high as 39°C (102.2°F), and his parents have been watching him at home. The history and physical examination are normal, and the child is fully immunized for age. Which of the following statements is not consistent with appropriate counseling of parents regarding their 3-year-old?
   A. Although acetaminophen may make him feel better, it will not prevent recurrence.
   B. He is at high risk for developing epilepsy later in life.
   C. It is safe for him to go home with the parents and do not lead to brain damage.
   D. Seizures with fever are common in young children and not evident on ED evaluation.
   E. There is no need to start any antiepileptic medication.

Answer: B. In general, a child between 6 months and 5 years who has a normal neurologic examination and has had a brief seizure in the setting of fever can be assumed to have a simple febrile seizure. Future epilepsy is not predicted and is unlikely in children with simple febrile seizures.

174.6. Which one of the following statements best describes the signs and symptoms associated with pediatric brain tumors?
   A. At the time of diagnosis, most patients with brain tumors have associated symptoms, such as nausea, vomiting, visual effects, problems with walking, weakness, changes in personality or school performance, or speech changes.
   B. Headaches are never the first symptom of a pediatric brain tumor.
   C. Most pediatric brain tumors are diagnosed within the first month after symptom onset.
   D. Papilledema is one of the least common neurologic findings in children with brain tumors.

Answer: A. Of patients with brain tumors, most have some of the associated signs or symptoms noted in choice A. Headaches may be the first symptom of a pediatric brain tumor, although the frequency of this presentation increases with age. Papilledema is one of the more common neurologic findings, along with abnormal eye movements, ataxia, abnormal tendon reflexes, and abnormalities on the visual examination. CT scanning is usually not performed with the first sign of a headache unless clinically indicated.

174.7. A 10-year-old boy is brought in by his mother for gait imbalance. He is alert and oriented to person, place, and time, and he has a negative drug or alcohol screen. He has a wide-based gait. What should be the next step in management?
   A. Admission and neurologic evaluation
   B. Discharge home if CT scan is negative
   C. Perform a lumbar puncture
   D. Reassurance and primary care referral
   E. Start sepsis evaluation

Answer: A. Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or the sudden development of a wide-based “drunken” gait. History should include recent infection, injury, inadvertent drug ingestion, or other family members with the same problem. Children with ataxia usually require admission for a complete evaluation. Consultation with a pediatric neurologist should be sought for patients in whom the cause of the ataxia is not evident on ED evaluation.

174.8. A 14-year-old girl with a history of migraines presents to the ED with the complaint of being unable to move her left side following a severe right-sided headache. Which of the following statements best describes her management?
   A. Imaging, analgesics, and admit to the hospital because symptoms may last for days.
   B. Immediate thrombolytics
   C. Inpatient vasculitis evaluation is indicated.
   D. She can be safely discharged home, and the symptoms will resolve in an hour.

Answer: A. Hemiplegic migraine is characterized by the sudden onset of hemiparesis or hemisensory loss followed by headache in the contralateral hemisphere. This type of migraine is seen more frequently in children than adults. Although symptoms usually last for hours or days, affected individuals are rarely left with permanent deficits.

174.9. A mother brings in her 4-year-old son for periods of lip smacking that occur multiple times per week and last several minutes. During these episodes, he may turn his head to her when she calls, but he does not speak. You suspect which of the following condition?
   A. Complex partial seizure
   B. Generalized seizure
   C. Infantile spasm
   D. Lennox-Gastaut syndrome
   E. Simple partial seizure

Answer: A. In complex partial seizures, the patient has a change in level of awareness and may exhibit bizarre behaviors including staring, lip smacking, wandering, or picking at clothing. In simple partial seizures, the patient has no change in mentation. Lennox-Gastaut syndrome is characterized by mental retardation, multiple seizure types, and a classic EEG pattern of slow spike and wave. Infantile spasms manifest during the first year of life and consist of rapid, jackknife flexor or extensor spasms that appear in clusters.
PRINCIPLES

Anatomy and Physiology

Several factors distinguish the pediatric musculoskeletal system from that of the adult. The most striking difference is the presence of the physis (the growth plate), made up of proliferating cartilage cells between the metaphysis and epiphysis. The physis is the weakest part of the bone and more likely to separate before the adjacent tendon or ligament tears, making sprains less frequent and physeal injuries common.

Children also have a thick, physiologically active periosteum, which is easily stripped from the bony cortex. The periosteum acts as a tether to reduce the amount of fracture displacement and, when it remains intact, aids in fracture reduction. The great bone-forming potential of the periosteum also facilitates the healing process. As a result, callus formation is vigorous, and nonunion almost never occurs.Growing bone is more porous, more pliable, and less dense than adult bone, making children more susceptible to fractures. Although less force is required to cause deformation, pediatric bone is more likely to buckle when it is compressed or bow when it is bent. Finally, because the bones are still growing, the potential for remodeling is greater. Growth can often compensate for postreduction imperfections in apposition and alignment, with deformities occurring in the plane of motion having the greatest potential for remodeling.

Fracture Patterns

Pediatric fracture descriptions include bone location (diaphysis, metaphysis, physis, or epiphysis), relationship of fracture fragments to one another (angulation and displacement), and relationship of fracture fragments to adjacent tissue (open or closed). Children develop fracture configurations not found in the adult population. Pediatric fractures can be classified as follows:

- Plastic deformation. Bone is bowed, with no obvious cortical disruption.
- Torus fracture (buckle fracture). Buckling of bone without cortical disruption tends to occur from compression failure at the metaphyseal-diaphyseal junction (Fig. 175.1). Distal radius buckle fractures may be immobilized with a Velcro wrist splint.1,3 These can be removed by the family or primary care provider in 3 to 4 weeks.
- Greenstick fracture. The bone is disrupted, along with one cortex; the periosteum on the fracture’s compression side remains intact (Fig. 175.2). In the emergency department (ED), minimally angulated (<10 degrees) distal radius greenstick fractures can be immobilized with a splint4 and patients referred to an orthopedic specialist within 1 week.
- Complete fracture. The fracture propagates completely through the bone involving both cortices; these include fractures that are transverse (Fig. 175.3), spiral (Fig. 175.4), oblique, and comminuted (Fig. 175.5).

Although injuries to the physis can occur at any age, they are more common during rapid skeletal growth. The Salter-Harris classification system is the most frequently used tool to describe physeal injuries. This classification system is based on the extent of involvement of the physis, epiphysis, and joint (Table 175.1). Types I and II Salter-Harris fractures (Figs. 175.6 and 175.7) do not involve the germinal layer of the growth plate, making the risk for growth arrest small. In general, the higher the Salter-Harris classification (Salter-Harris types III–V), the greater the damage to the growth plate, and thus the greater the likelihood of growth arrest or limb length abnormalities (Figs. 175.8 to 175.10). Type II fractures account for approximately 75% of all growth plate injuries.

SPECIFIC DISORDERS

Clavicle Fracture

The clavicle is a frequently broken bone in children. The physis of the clavicle does not close until the third decade (someone in their 20s) and is at risk for injury until that time. Midshaft fractures account for approximately 85% of all clavicle fractures. The usual mechanism of injury is a fall on the shoulder or, less commonly, direct trauma to the bone itself. The child typically supports the affected side with the other hand and tilts the head toward the side of the fracture. Physical examination reveals point tenderness at the fracture site, with or without an obvious bone deformity. Pain usually limits range of motion of the shoulder.

Although complications are rare, due to the proximity of the clavicle to the great vessels and brachial plexus, a thorough neurovascular evaluation should be performed. Posterior sternoclavicular displacement can cause injury to the trachea, esophagus, and subclavian vessels, whereas lateral clavicular displacement can result in injury to the brachial plexus. Middle third fractures have been associated with neurovascular bundle injuries, pulmonary injury, and pneumothorax.

An anteroposterior (AP) radiograph of the clavicle (Fig. 175.11) confirms the diagnosis. If clinical suspicion is high, and the AP view does not reveal a fracture, a 30-degree cephalic view can be helpful. With proximal fractures or posteriorly displaced fractures or dislocations, associated neurovascular injuries may be identified by computed tomography (CT) or duplex ultrasonography.

Clavicle fractures do not usually require anatomic reduction for healing or function; treatment should be directed at maintenance of comfort with splinting, ice, and analgesics. Figure-of-eight splinting is not recommended due to a risk for brachial plexus palsy with long-term use. A sling with or without a swath should be used to provide comfort by supporting the upper extremity and providing the suspensory forces usually maintained by the clavicle. Most clavicle fractures heal without complications, except for the development of bony callus at the fracture site; the younger the patient, the greater the potential for remodeling of this deformity. Younger children generally require shorter periods of immobilization (2–4 weeks) than adolescents and adults (4–8 weeks).

Rehabilitation includes early range of motion and strengthening of the rotator cuff. Immediate orthopedic consultation should be obtained for clavicle fractures that are open or associated with
Clavicle fractures can occur during childbirth and represent more than 90% of obstetric fractures. Displaced clavicle fractures are identified by crepitus, edema, lack of movement of the affected extremity, asymmetric bone contour, and crying with passive motion. Nondisplaced fractures may not be noticeable until a bony callus becomes apparent at 10 days of age. The presence of a clavicle fracture should prompt further investigation for accompanying brachial plexus injury.
CHAPTER 175  Musculoskeletal Disorders

Supracondylar fractures are classified according to mechanism of injury as flexion or extension injuries. The extension type of injury constitutes 95% of all supracondylar fractures and typically results from a hyperextension injury incurred from a fall onto the outstretched arm. This mechanism results in failure of the anterior cortex and displacement of the distal fragment posteriorly. With extension-type fractures, the degree of displacement and continuity of the cortex are defined by the Gartland classification (Table 175.2). In the less common flexion type of supracondylar fracture, the elbow is flexed when it hits the ground. This mechanism results in a supracondylar fracture with anterior displacement of the distal fragment and failure of the cortex posteriorly.

Children with supracondylar fractures may present with anything from mild swelling and elbow pain to a grossly displaced humerus. Due to the risk of neurovascular damage, manipulation of the elbow should be avoided. Children with extension-type supracondylar fractures hold the affected arm in extension with an S-shaped configuration of the elbow and exhibit a prominence at the olecranon. Children with flexion-type supracondylar fractures hold the arm in flexion and exhibit an empty space where the olecranon should be. Motor and sensory functions should be

**Supracondylar Fractures of the Humerus**

Supracondylar fractures represent the most common elbow fractures in children younger than 8 years. Until that age, the tensile strength of the ligaments and joint capsule is greater than that of the bone itself, and the weaker bones yield to the stronger ligament complex around the joint.
PART V Special Populations | SECTION ONE The Pediatric Patient

The pediatric patient to the injury should have compartment pressures measured. Unrecognized ischemic injury can result in Volkmann’s ischemic contracture, characterized by fixed elbow flexion, forearm pronation, wrist flexion, metacarpophalangeal joint extension, and interphalangeal flexion. A complete examination of the upper extremity should be completed because concomitant injuries involving the wrist or forearm occur in approximately 10% of patients.

evaluated by assessing the radial, ulnar, and median nerves (Table 175.3). Two-point discrimination of more than 5 mm on the fingers indicates a deficit. Vascular assessment should include evaluation of the radial and brachial pulses and capillary refill of the hand. Due to risk of compartment syndrome of the forearm, patients with pain on flexion or extension of the fingers, forearm swelling, tenseness or tenderness, or pain that is disproportionate

Radiographic evaluation of an elbow injury includes an AP view of the extended elbow, oblique view, and lateral view of the flexed elbow. The elbow is largely cartilaginous during early childhood, and the six secondary centers of ossification around the elbow can camouflage or be mistaken for fractures (Fig. 175.12). These ossification centers can be remembered by the mnemonic CRITOE—capitellum, radius, internal (medial) epicondyle, trochlea, olecranon, and external (lateral) epicondyle. The approximate ages at which these sites ossify are 1, 3, 5, 7, 9, and 11 years, respectively (Table 175.4).

Bone relationships are helpful in the evaluation of a radiograph for a supracondylar fracture (Fig. 175.13). A true lateral view should demonstrate a figure-of-eight appearance of the distal humerus, with bisection of the capitellum by the anterior humeral...
line. If the capitellum falls posterior to this line, an extension-type supracondylar fracture is likely. In all views, the proximal end of the radius and radial neck should point to the capitellum. Baumann’s angle is helpful in diagnosing a subtle supracondylar fracture (Fig. 175.14). This angle is formed by a line drawn to follow the growth plate of the capitellum transected with a line that runs perpendicular to the axis of the humerus. The angle should be approximately 75 to 80 degrees. Baumann’s angle should be the same in both elbows; differences between elbows can be used to detect subtle supracondylar fractures. In children younger than 3 years, difficult to distinguish bone landmarks limit the utility of Baumann’s angle.

Fat pads also provide a means for the detection of occult supracondylar fractures. A lateral radiograph with the elbow flexed at 90 degrees is useful for evaluating anterior and posterior fat pads. An anterior fat pad protruding from the coronoid fossa is normal unless the pad is bulging or in the shape of a ship’s sail (the so-called sail sign). The posterior fat pad sits snugly within the olecranon fossa and should never be seen; the presence of a posterior fat pad suggests an occult fracture around the elbow. Patients with a posterior fat pad, but no obvious fracture (Fig. 175.15) should be splinted and given a 1-week orthopedic follow-up. After plain radiography, if the diagnosis remains in question, ultrasound imaging may be useful in infants, and magnetic resonance imaging (MRI) may be useful in older children.

ED treatment of supracondylar humeral fractures is determined by the degree of displacement and neurovascular status. A patient with a pale, pulseless cold hand should receive emergency consultation with an orthopedic surgeon. If an orthopedic surgeon is not immediately available, and the vascular supply has not been restored, reduction should be attempted (Fig. 175.16), taking care not to entrap the brachial artery and median nerve. If the hand does not become warm and pink, the reduction may be attempted a second final time. If perfusion is not reestablished after a second attempt, the child should receive emergent operative intervention.

A supracondylar fracture with a pulseless hand that is warm and pink does not need to be reduced immediately. The arm should be splinted as it lies to prevent further vascular compromise.

Garland type I fractures can be splinted in the ED, with the arm maintained in 90 degrees of flexion and neutral rotation. Garland type II fractures require immediate orthopedic consultation and should be treated in the operating room by closed reduction and percutaneous pinning or open reduction and internal fixation. Treatment of type II fractures is controversial. Some surgeons operatively reduce and pin, whereas others perform closed reduction and cast.

Neurovascular compromise complicates 11.3% of displaced supracondylar fractures—the anterior interosseous branch of the median and radial nerves are at risk of damage in extension-type injuries; the ulnar nerve is damaged in flexion-type injuries. Most nerve injuries are neurapraxias that resolve spontaneously. Although motor function usually returns within 12 weeks, sensory function may not return for 6 to 12 months. Brachial artery injuries, including arterial entrapment, laceration, intimal tears, thrombosis, and compression from compartment syndrome, occur in approximately 40% of patients. Fortunately, the brachial artery has many branches around the elbow, allowing flow to the forearm and hand when the brachial artery is injured. Untreated vascular injury can also result in Volkmann’s ischemic contracture and permanent limb disability. Some supracondylar fractures heal with a gunstock deformity with varus, hyperextension, and medial rotation of the limb.

**Monteggia’s Fracture-Dislocation**

Monteggia’s fracture-dislocations are characterized by a fracture of the proximal third of the ulna plus dislocation of the radial head. The radiographic evidence can be subtle, with only a minor greenstick fracture or bowing of the ulna. Isolated ulna fractures are rare in children; therefore, with all such fractures, a dislocation of the radial head should be excluded (Fig. 175.17). Radiographs should be examined for the ulnar bow sign. This is found when any portion of the ulna lies anterior to a line drawn along the posterior cortex of the ulna on the lateral view.

Immediate orthopedic consultation should be obtained for closed reduction of the radial head dislocation and repair of the ulna fracture. Complications include permanent radial head dislocation, valgus deformity of the arm, loss of pronation, and late radial nerve palsy.

**Nursemaid’s Elbow**

Radial head subluxation, also known as annular ligament displacement or nursemaid’s elbow, has been estimated to represent about 1% of injury-related ED visits. It typically occurs when axial traction is placed on an extended and pronated arm, as when the child is pulled up or swung by the arms. It also may occur when the child falls onto the outstretched arm, sustains minor direct trauma to the elbow, or simply twists the arm. Subluxation occurs
Steps

When the radial head slips out of the annular ligament, trapping the ligament in the radiocapitellar joint (Fig. 175.18).

Nursemaid’s elbow occurs in children a few months to 5 years of age and has a peak incidence between 2 and 3 years. Children present with the acute onset of arm pain that may or may not be localized to the elbow. The affected arm is typically held against the body, with the elbow slightly flexed and the arm pronated. Physical examination is significant for lack of swelling, erythema, ecchymosis, or deformity. Examination may reveal mild tenderness of the radial head. Pain is elicited with supination, pronation and elbow flexion. The diagnosis of nursemaid’s elbow is made clinically, and imaging is not necessary. Radiographs should be obtained for significant point tenderness, swelling, or ecchymosis. Ultrasound imaging may demonstrate a widened space between the radial head and the capitellum.

Radial head subluxation is easily reduced without sequelae. With the flexion-supination technique, the affected elbow is gripped with the emergency clinician’s thumb over the radial head and, with the other hand, the emergency clinician flexes and supinates the patient’s arm. As the radial head relocates, the emergency clinician feels it click or clunk under his or her thumb. Using the hyperpronation technique, the child’s affected elbow is held with the emergency clinician’s thumb over the radial head, and the forearm is hyperpronated. Success rates are approximately 85% with supination and 95% with hyperpronation. Pronation may be less painful to the patient and is the reduction method of choice. After successful reduction, the child typically uses the arm normally within 10 to 20 minutes. This may be delayed in younger children or when the injury occurred more than 4 to 6 hours before reduction. Neither splinting nor orthopedic referral is required after a successful reduction. Recurrence is common, and parents should be cautioned to avoid traction on the forearm.

Failure to reduce a nursemaid’s elbow may result from improper reduction technique, edema, or disruption of the annular ligament. If two attempts at reduction are unsuccessful, a posterior splint should be applied, with the elbow kept at 90 degrees and the forearm in supination. Orthopedic follow-up should be arranged for the next day.

**Toddler’s Fracture**

Toddler’s fractures are oblique nondisplaced fractures of the distal tibia caused by low-energy torsional forces applied to the porous bone of infants and young children. The peak incidence is between 9 and 36 months of age but it can occur in children as old as 6 years. The mechanism of injury can be as mild as the child’s twisting on the leg while walking or a fall from an insignificant height; the mechanism may even be unknown. The child will limp or may refuse to walk on the affected leg. Some children will revert to crawling and can crawl without pain. Examination may show mild swelling of the lower leg and point tenderness along the tibia. Gentle twisting of the lower part of the leg may elicit pain.

AP and lateral radiographs may reveal a spiral or oblique fracture extending downward and medially through the distal third of the tibia (Fig. 175.19). An internal oblique radiograph is helpful if evidence of fracture is absent on the AP or lateral view. If no fracture is apparent, the child should be splinted for comfort. Radiography repeated in 10 days, at which time periosteal new bone or sclerosis of the fracture edges will make the fracture visible. If findings on these radiographs are normal and the child is still limping, further imaging should be undertaken to rule out osteomyelitis and malignant neoplasm. Ultrasonography can be considered for the detection of occult fractures in toddlers and in older children. Treatment of a toddler’s fracture consists of a long leg cast with the knee flexed for approximately 3 weeks.

**Developmental Dysplasia of the Hip**

**Principles**

Developmental dysplasia of the hip (DDH), formerly known as congenital dislocation of the hip, denotes a wide spectrum of
Clinical Features

DDH may be diagnosed at birth or, despite frequent and appropriate physical examinations, may not be discovered until later in life. The clinical manifestations of DDH vary with the severity of the dysplasia and the progressive changes that occur over time. Up to 6 months of age, the diagnosis of DDH is based on physical examination findings, including leg length, skinfold, and range of motion asymmetry, and abnormal findings on the Barlow provocative test and Ortolani reduction maneuver. Skinfold asymmetry can be
or asymmetry in hip flexion, abduction, and external rotation should be referred for orthopedic consultation.

Cornerstones for diagnosing DDH in young infants are the Ortolani reduction maneuver and Barlow provocative test. The Ortolani reduction maneuver is performed in an attempt to reduce a dislocated hip into normal position, and the Barlow provocative test detects a lax (subluxable) or easily dislocated hip (Box 175.1). Abnormal findings are the presence of a clunk with the Ortolani test and any abnormal movement between the femoral head and acetabulum with the Barlow maneuver.

After approximately 4 to 6 months of age (ie, when soft tissue contractures have developed), the Ortolani and Barlow tests are less reliable, and range of motion abnormalities become more apparent. Parents may notice limited or asymmetric leg movements or difficulty with diapering. Findings on examination include limited abduction (Fig. 175.21), relative shortening of the ipsilateral femur (Galeazzi’s sign; Fig. 175.22), and skinfold asymmetry.

With the onset of walking, gait asymmetry or asymmetrical in-toeing or out-toeing is a clue to the presence of DDH. Adduction and flexion contractures, Galeazzi’s sign, hyperlordosis, and waddling gait are common features. Patients may exhibit Trendelenburg’s sign—while standing, the patient lifts one leg up at a time and, because the gluteal muscles are weakened on the affected side, the pelvis drops to the opposite side.

**Diagnostic Testing**

Radiographs of infant hips are extremely difficult to interpret. Before the femoral head ossifies at 3 to 6 months of age, an
abnormal relationship between the upper end of the femur and acetabulum may not be apparent. In infants with unstable but nondislocated hips, radiographs will show the hips in normal position. Before femoral head ossification, a better diagnostic test is ultrasonography. Nondislocated but unstable hips can have ultrasound screening delayed until 4 to 6 weeks of age, when the normal laxity of the hip resolves. Children with dislocated hips, however, should undergo an immediate ultrasound examination. Plain radiographs are useful when the femoral epiphysis ossifies. A standard AP radiographic view of the pelvis with both legs extended in neutral abduction is sufficient for diagnosis. Radiographic findings may include displacement of Shenton’s line—a curvilinear line defined by the medial border of the femoral neck and superior border of the obturator foramen—and a widened acetabular angle. Angles greater than 30 degrees are abnormal, and those greater than 40 degrees indicate dislocation (Fig. 175.23).

Management

Treatment of DDH is most successful when begun early. Patients with untreated abnormalities of the hips that persist beyond the newborn period are at risk for osteoarthritis, pain, abnormal gait, leg-length discrepancy, and decreased agility. Thus, all children who are seen in the ED should have their hips examined until they are able to walk. Neonates who have a dislocated hip at birth should be referred to a pediatric orthopedist immediately. When a newborn has a loose but nondislocated hip, referral can be made within 2 weeks, because most ultrasound and physical examination abnormalities detected in the neonatal period resolve by 2 to 4 weeks of age. Children with loose hips who are seen after the newborn period should be promptly referred to an orthopedic surgeon.

The goal of treatment of DDH is concentric reduction and stabilization of the hip and resolution of dysplastic features of the bone and cartilage. The two most important complications are failure to achieve these goals and aseptic necrosis of the femoral head. In the first 6 months of life, use of the Pavlik harness is the mainstay of treatment. This harness is a dynamic splint that allows movement while preventing hip extension or adduction. Other treatment options include the von Rosen and other similar splints. If these modalities are unsuccessful, application of a hip spica cast is considered. If DDH is diagnosed after 6 months of age, the use of a hip spica cast or fixed orthosis is often required. Most children older than 18 months require surgical reconstruction. Beyond the age of 6 years in bilateral cases and 8 to 10 years in unilateral cases, repair is not usually attempted, because the risks of aseptic necrosis and treatment failure are too high.

Pediatric Hip Pain

Principles

Hip pain in children is an extensive topic, with myriad causes (Box 175.2). The extensive differential diagnosis precludes an in-depth review of the topic in this chapter, but an overview of some of the more common causes of hip pain in children is presented.

Fig. 175.22. Galeazzi’s sign in a 7-month-old girl with left hip dislocation. Apparent inequality of femur length is manifested as asymmetry in the level of the patient’s knees. (From Storer SK, Skaggs DL: Developmental dysplasia of the hip. Am Fam Physician 74:1310–1316, 2006.)

Fig. 175.23. Anteroposterior radiographs obtained in a 7-month-old girl with developmental dysplasia of the left hip. A, The horizontal line is Hilgenreiner’s line; the vertical lines are Perkin’s lines. Note that the femoral head on the right (normal) side lies in the inferomedial quadrant formed by those lines. The left hip is dislocated; its femoral head lies in the superolateral quadrant. B, Shenton’s line is disrupted on the left (dislocated) hip. (From Storer SK, Skaggs DL: Developmental dysplasia of the hip. Am Fam Physician 74:1310–1316, 2006.)
Transient Synovitis. Transient synovitis is one of the most common causes of hip pain in childhood, occurring in up to 3% of children. It is a self-limited condition caused by a nonpyogenic inflammatory response of the synovium. The cause of transient synovitis is unknown. Some have hypothesized an association with active or recent infection, trauma, or allergic hypersensitivity. It may occur in infants, adolescents, and adults; its peak incidence is between 3 and 9 years of age. Boys are affected more commonly than girls, and there is a slight predilection for the right side. Less than 5% of cases are bilateral. Its onset may be acute or insidious. Transient synovitis may affect the hips or the knees.

Patients commonly report pain in the hip or groin, but pain can also refer to the knee (femoral nerve), medial thigh (obturator nerve), or buttock (sciatic nerve). Affected patients may walk with limited laboratory testing and AP and frog leg lateral radiography. Unless the diagnosis, ultrasonography can be used. Effusions are present in 60% to 70% of cases of transient synovitis; however, this is a nonspecific finding, and the presence of an effusion on ultrasonography cannot be used to distinguish transient synovitis from other causes of hip pain.

A complete blood count, CRP level, and ESR should be determined, and radiography should be performed. Unless the diagnosis is in question, there is no need to aspirate the joint. Patients with severe symptoms—absent range of motion, ill-appearing, or inability to bear weight—fever higher than 38.5°C (101.3°F), and elevated ESR (>240 mm/hr) or CRP (>2.0 mg/dL) or >20 mg/L) should undergo joint aspiration.

Most cases of transient synovitis can be managed at home with close follow-up by the child’s primary care provider within 24 hours. Treatment of transient synovitis is directed at rest of the affected joint and NSAIDs. Temperatures should be monitored, and any fever reported to the physician. Children are allowed a gradual return to activity as the pain subsides, and full activity is permitted when the hip is completely pain-free, with no evidence of a limp.

The prognosis for children with transient synovitis is excellent; 75% have complete resolution of pain within 2 weeks and 88% within 4 weeks. The remainder may have less intense but persistent pain for up to 8 weeks. Relapse is infrequent and long-term sequelae rare. A small number (2%) of cases of transient synovitis follow a clinical and radiographic course consistent with that of Legg-Calvé-Perthes disease. Children with persistent symptoms should undergo ultrasonography to evaluate for the presence of an effusion; persistent joint effusion beyond 6 weeks may be associated with the subsequent development of Legg-Calvé-Perthes disease.

Acute Septic Arthritis. Septic arthritis refers to microbial invasion and infection of the joint space. Bacterial pathogens are common in patients with acute septic arthritis, whereas fungal and mycobacterial pathogens tend to be associated with a more indolent septic arthritis. Acute septic arthritis occurs in all age

### Specific Disorders and Injuries

- **Transient Synovitis.** Transient synovitis is one of the most common causes of hip pain in childhood, occurring in up to 3% of children. It is a self-limited condition caused by a nonpyogenic inflammatory response of the synovium. The cause of transient synovitis is unknown. Some have hypothesized an association with active or recent infection, trauma, or allergic hypersensitivity. It may occur in infants, adolescents, and adults; its peak incidence is between 3 and 9 years of age. Boys are affected more commonly than girls, and there is a slight predilection for the right side. Less than 5% of cases are bilateral. Its onset may be acute or insidious. Transient synovitis may affect the hips or the knees.

- **Patients commonly report pain in the hip or groin, but pain can also refer to the knee (femoral nerve), medial thigh (obturator nerve), or buttock (sciatic nerve). Affected patients may walk with a limp or may refuse to walk at all. The leg is held in flexion, with slight abduction and external rotation. On examination, passive movement may be pain-free, with a slightly decreased range of motion with extreme internal rotation or abduction. Most children with transient synovitis are appear well, although some have a low-grade fever and malaise.**

- **The diagnosis of transient synovitis is one of exclusion and relies on the history and physical examination, in combination with limited laboratory testing and AP and frog leg lateral radiographs of the pelvis. Laboratory tests are used to help distinguish children with transient synovitis from those with septic arthritis. In transient synovitis, laboratory values may be normal or may reveal mild elevations in the white blood cell (WBC) count, C-reactive protein (CRP) level, and erythrocyte sedimentation rate (ESR), consistent with a nonspecific inflammatory process.**

- **Multiple studies have attempted to define criteria to help differentiate transient synovitis from septic arthritis. Four independent multivariate predictors of septic arthritis have been found (Kocher criteria)—fever, inability to bear weight, ESR of 40 mm/hr or higher, and serum WBC count higher than 12,000 cells/µL. Patients with three of the four predictors had a 93% chance of having septic arthritis, and those with all four had a 99% likelihood. A subsequent study to validate these findings showed that patients with none of these predictors had a 2% probability of septic arthritis, with one predictor, a 9.5% probability, with two predictors, a 35% probability, with three predictors, a 73% probability, and with all four predictors, a 93% probability of septic arthritis.**

- **When this algorithm was tested at another institution, however, the presence of all four Kocher criteria predicted septic arthritis only 59% of the time. A CRP level can also help risk-stratify children for septic arthritis. In a study of children with hip effusions, children with the ability to bear weight combined with CRP values lower than 20 mg/L had less than 1% risk of septic arthritis. Children unable to bear weight with CRP values higher than 20 mg/L had a 74% probability of having septic arthritis.**

- **Thus, in children who are able to ambulate, have minimal pain after treatment with nonsteroidal antiinflammatory drugs (NSAIDs), and have normal inflammatory markers, outpatient management with close primary care follow-up is reasonable.**

- **Radiographs of the hip and pelvis may be normal or nonspecific with transient synovitis but are helpful in excluding other diseases. Radiographic findings consistent with transient synovitis include medial joint space widening, accentuated pericapsular shadow, and Waldenström’s sign, which is lateral displacement of the femoral epiphysis, with surface flattening secondary to effusion. However, these findings also are apparent in Legg-Calvé-Perthes disease and, if present, need close follow-up or further investigation with MRI. If joint aspiration is necessary to clarify the diagnosis, ultrasonography can be used. Effusions are present in 60% to 70% of cases of transient synovitis; however, this is a nonspecific finding, and the presence of an effusion on ultrasonography cannot be used to distinguish transient synovitis from other causes of hip pain.**

- **A complete blood count, CRP level, and ESR should be determined, and radiography should be performed. Unless the diagnosis is in question, there is no need to aspirate the joint. Patients with severe symptoms—absent range of motion, ill-appearing, or inability to bear weight—fever higher than 38.5°C (101.3°F), and elevated ESR (>240 mm/hr) or CRP (>2.0 mg/dL or >20 mg/L) should undergo joint aspiration.**

- **Most cases of transient synovitis can be managed at home with close follow-up by the child’s primary care provider within 24 hours. Treatment of transient synovitis is directed at rest of the affected joint and NSAIDs. Temperatures should be monitored, and any fever reported to the physician. Children are allowed a gradual return to activity as the pain subsides, and full activity is permitted when the hip is completely pain-free, with no evidence of a limp.**

- **The prognosis for children with transient synovitis is excellent; 75% have complete resolution of pain within 2 weeks and 88% within 4 weeks. The remainder may have less intense but persistent pain for up to 8 weeks. Relapse is infrequent and long-term sequelae rare. A small number (2%) of cases of transient synovitis follow a clinical and radiographic course consistent with that of Legg-Calvé-Perthes disease. Children with persistent symptoms should undergo ultrasonography to evaluate for the presence of an effusion; persistent joint effusion beyond 6 weeks may be associated with the subsequent development of Legg-Calvé-Perthes disease.**

- **Acute Septic Arthritis.** Septic arthritis refers to microbial invasion and infection of the joint space. Bacterial pathogens are common in patients with acute septic arthritis, whereas fungal and mycobacterial pathogens tend to be associated with a more indolent septic arthritis. Acute septic arthritis occurs in all age
groups but is more common in children; 70% of cases occur in children younger than 4 years, with the peak incidence between 6 and 24 months. Boys are affected twice as frequently as girls. Predisposing factors include preceding viral infection, trauma, immunodeficiency, hemoglobinopathy, hemophilia with recurrent hemarthroses, diabetes, injection drug abuse, rheumatoid arthritis, and intraarticular injections or operations. Septic arthritis involves the lower extremities in 75% of cases, with the knee the most commonly involved and the hip second most commonly involved. More than 90% of the cases are monoarticular. A history of trauma is elicited in one-third of cases.12

Most cases of acute septic arthritis are spread hematogenously, although infection can result from direct inoculation or spread from adjacent tissues. After bacteria enter the joint space, they bind to bone and cartilage, initiating an inflammatory response that breaks down the joint by two mechanisms—directly through the effects of proteolytic enzymes and indirectly through pressure necrosis caused by accumulation of purulent synovial fluid. Contiguous spread of infection from osteomyelitis to the joint space occurs in approximately 10% of cases and is more common in newborns and young infants. In these children, blood vessels cross the physis, thereby connecting the metaphysis and epiphysis, facilitating direct extension of osteomyelitis into the joint spaces. Contiguous septic arthritis with *S. aureus* osteomyelitis has also been documented in older children without these structural differences.13

The most common bacterial causes of septic arthritis are listed in Table 175.5. Overall, *S. aureus* is the most common cause of septic arthritis and infection in children; community-acquired, methicillin-resistant *S. aureus* (MRSA) accounts for up to 65% of *S. aureus* infections.14 Patients with MRSA osteoarticular infection have a more acute onset of illness, with higher fever and a more severe and complicated clinical course. In neonates, group B streptococci and gram-negative organisms are common causes. In addition to the organisms listed in Table 175.5, other causative organisms include *Neisseria gonorrhoeae* in neonates and sexually active adolescents, *Pseudomonas aeruginosa* and *Candida* spp. in injection drug abusers, *Salmonella* spp. in children with sickle cell disease, and gram-negative bacteria in immunosuppressed children.

*Kingella kingae*, a fastidious gram-negative coccobacillus that colonizes the respiratory and oropharyngeal tracts in children, has been implicated as a common cause of osteoarticular infections in young children. In one study, *K. kingae* was found to be the causative agent in 82% of osteoarticular infections, with the authors reporting a more benign presentation than is seen with other pathogens.13 *K. kingae* is susceptible to a wide array of antibiotics, including the third-generation cephalosporins that are given empirically to young children with suspected septic arthritis.

The clinical picture of septic arthritis varies with age. Infants tend to have fever, failure to feed, lethargy, pseudoparalysis of the extremity, and pain when being handled. Most older children have systemic signs and symptoms of fever, malaise, poor appetite, and irritability, as well as localized symptoms of pain and refusal to move the affected joint. If the lower part of the body is involved, patients may limp or refuse to walk. The physical examination reveals local erythema, warmth, and swelling. If the hip is affected, it often is held in flexion, abduction, and external rotation. Range of motion is decreased because of pain and muscle spasm, and passive joint movement is painful. In infants, joint dislocation may be observed.

Laboratory evaluation of septic arthritis should include a WBC count, ESR and CRP levels, blood cultures, and evaluation of joint fluid. (Use of the WBC count and ESR was discussed earlier in the section on transient synovitis.) The ESR rises 24 hours or longer after the onset of signs and symptoms of infection, so it may not be helpful during the first day of illness. The CRP level rises more quickly than the ESR, typically is elevated at the time of the initial evaluation and, with appropriate therapy will normalize within 1 week; by contrast, the ESR will not normalize for more than 1 month. As such, CRP is a better marker for response to treatment.

In patients with septic arthritis, the peripheral WBC count and ESR and CRP levels are generally elevated, although WBC counts and acute-phase reactants may be normal, especially with *K. kingae* infection.5,16 Yagupsy and colleagues have found that the clinical and laboratory features in young children (6–27 months of age) with *K. kingae* septic arthritis and transient synovitis were so similar that the Kocher algorithm was not helpful and, even without fever or leukocytosis, they recommended blood cultures and nucleic acid amplification.17 For patients without fever who are able to ambulate and have normal inflammatory markers, we recommend further testing, such as a polymerase chain reaction (PCR) assay of the blood or joint fluid, if symptoms worsen or persist beyond 3 days.

Blood cultures should be included in the evaluation of a child with suspected septic arthritis. Although cultures are positive in less than 50% of cases, positive cultures can help direct antibiotic treatment. If *N. gonorrhoeae* infection is suspected, special media are required for cultures of joint fluid, blood, pharynx, skin lesions, cervix, urethra, vagina, and rectum. Urine, urethral, cervical, and vaginal specimens also can be obtained for nucleic acid amplification testing. If the patient has signs or symptoms of pharyngitis, a throat swab should be sent for culture of *Streptococcus pyogenes*. Patients with *K. kingae* musculoskeletal infection tend to have oropharyngeal colonization and culture or PCR assay of the oropharynx should be performed.18,19

If septic arthritis is being considered, joint aspiration should be performed without delay and the synovial fluid sent for Gram staining, aerobic and anaerobic cultures, cell count with differential count, glucose determination, and PCR assay.20 The synovial fluid in patients with septic arthritis tends to be turbid or grossly purulent, with a WBC count higher than 40,000 cells/μL and a

septic arthritis with adjacent osteomyelitis has been found in 59%
to 68% of patients and more likely if three or more of the follow-
were present: age older than 3.6 years, CRP level more than
13.8 mg/L, symptoms for more than 3 days, platelets less than
314,000/µL, and absolute neutrophil count (ANC) more than 8.6
x 10^3 cells.

Septic arthritis requires hospital admission, antibiotics, and
surgical intervention. Surgical options range from needle aspira-
tion to open surgical drainage. Indications for surgical drainage
in children with septic arthritis include involvement of the hip
joint, presence of large amounts of pus or debris in the joint, locu-
ated fluid, recurrence of joint fluid after four or five aspirations,
and lack of clinical improvement within 3 days of the initiation
of appropriate therapy.

Empirical antibiotic therapy for septic arthritis is directed
against the most likely organisms, as dictated by the patient’s age
and comorbid conditions (see Table 175.5). To maximize culture
results, antibiotics should not be given until a specimen of joint
fluid is obtained. The emergency clinician must weigh the stability
of the patient and possible risk of sepsis with the time needed
to obtain synovial fluid. If the child is septic, empirical antibiotics
should be given, even if prior to aspiration of fluid. Initial treat-
ment should be parenteral to ensure adequate serum antibiotic
concentrations. In addition to antibiotics, a 4-day course of
intravenous dexamethasone (0.15 mg/kg qid for 4 days) may be
given before or within 2 hours of antibiotics because it can provide
symptom relief with less fever and local inflammation, fewer
acute-phase reactants, and shorter intravenous treatment time
without increased sequelae.

The mortality rate associated with septic arthritis has fallen to
less than 1%, but the morbidity remains significant. Sequelae
include leg-length discrepancy, persistent pain, limited range
of motion and ambulation, and ischemic necrosis of the femoral
head.

**Legg-Calvé-Perthes Disease.** Idiopathic avascular necrosis
of the proximal femoral head, also known as Legg-Calvé-Perthes
disease, is named after the men who independently described it
in the early 1900s. The cause remains unclear; theories are myriad
and research results conflicting. It usually occurs in those between
the ages of 3 and 12 years, with the peak incidence between the
ages of 5 and 7 years. Legg-Calvé-Perthes disease has been reported
in teenagers as well as in children as young as 2 years. Boys are
affected more frequently than girls, it is bilateral in up to 20% of
cases, and it is familial approximately 10% of the time. It is least
common in African Americans and East Asians and most common
in whites. There is increased incidence at higher latitudes.

Children with Legg-Calvé-Perthes disease initially exhibit a
limp of insidious and stuttering onset. Pain tends to be localized
to the groin or referred to the anteromedial aspect of the thigh or
knee region and is worse with activity, relieved by rest, and worse
at the end of the day. There is limited hip motion, particularly
abduction and internal rotation. Trendelenburg’s sign may be
present (see earlier, “Developmental Dysplasia of the Hip”)
accompanied by thigh, calf, and buttock atrophy secondary to
disuse. Advanced disease with femoral head collapse results in a
limb-length discrepancy.

Laboratory evaluation in Legg-Calvé-Perthes disease is useful
in ruling out other causes of hip pain (eg, septic arthritis) and
evaluating potential hormonal, metabolic, or genetic causes in
patients with bilateral hip involvement.

Legg-Calvé-Perthes disease is diagnosed and staged by AP and
femur lateral radiographs. Radiographs show the extent of
epiphyseal involvement and stage of disease. Radiographic “head
at-risk” signs associated with poor results include a radiolucent,
V-shaped, osteoporotic defect in the lateral epiphysis (Gage’s
sign), speckled calcification lateral to the capital epiphysis,
diffuse metaphyseal reaction (metaphyseal cysts), lateral capital femoral
epiphyseal subluxation, and a horizontal physis. MRI can provide
earlier and comprehensive information regarding the extent
of femoral head necrosis, as well as the anatomy of the head and
labrum. The addition of gadolinium enhancement shows femoral
head perfusion and provides additional prognostic information.
Arthrography is useful in evaluating the relationship between
the femoral head and acetabulum and aids in the assessment of range
of motion.

*PMNs, Polymorphonuclear leukocytes (neutrophils); WBC, white blood cell.*
There are four radiographic classification stages of Legg-Calvé-Perthes disease—initial, fragmentation, reossification, and healed. Radiographic findings in the initial stage include a femoral head that appears smaller than the opposite unaffected femoral head, widening of the medial joint space, subchondral lucent zone, subchondral collapse causing the crescent sign (Caffey’s sign; Fig. 175.24), irregular physeal plate, and blurry and radiolucent metaphysis. In the fragmentation phase, the repair aspects of the disease become more prominent. The epiphysis begins to fragment, and there are areas of radiolucency and radiodensity as new bone forms. During the reossification stage, the repair process continues as normal bone density returns, radiodensities replace radioluencies, and alterations in the shape of the femoral head and neck become apparent. The healed stage is the final radiographic stage of Legg-Calvé-Perthes disease, and radiographs of the proximal third of the femur will demonstrate residual deformities. Multiple prognostic classification systems of Legg-Calvé-Perthes disease have been devised; a poor prognosis is associated with greater degrees of deformity of the femoral head and acetabulum at maturity, disease onset in children 6 years or older, female gender, and prolonged duration of disease.

Children diagnosed with Legg-Calvé-Perthes disease should have an orthopedic consultation. Goals in the treatment of Legg-Calvé-Perthes disease are to improve range of motion, prevent deformity, limit growth disturbance, and prevent degenerative joint disease. Treatment is recommended for patients who have clinical and radiographic findings suggestive of a poor prognosis, and it should be started in the initial or fragmentation phase of the disease. The cornerstone of treatment of Legg-Calvé-Perthes disease is containment of the femoral head within the acetabulum to equalize pressure on the head and mold it to the acetabulum. Containment can be achieved nonoperatively or operatively and is determined on a case by case basis. Residual deformities resulting from Legg-Calvé-Perthes disease include morphologic changes in the femoral head (coxa magna, coxa brevis, and coxa irregularis), osteochondritis desiccans, femoroacetabular impingement, and early- or late-onset arthritis. Most patients develop osteoarthritis in their 30s and 40s, with the likelihood of arthritis linked to the sphericity of the femoral head.

Slipped Capital Femoral Epiphysis. A slipped capital femoral epiphysis (SCFE) involves posterior and inferior slippage of the proximal femoral epiphysis on the metaphysis. The femoral head sits securely in the acetabulum and separates from the femoral neck through the growth plate. The average annual incidence of SCFE ranges from 0.71 to 10.8/100,000 children, with rates affected by several factors: (1) race—higher prevalence in African Americans, Hispanics, and Pacific Islanders than whites; (2) geography—higher rates north of 40-degree latitude and in the northeastern and western United States; (3) gender—boys are affected twice as frequently as girls; and (4) underlying medical conditions—more frequent with endocrinopathies, renal osteodystrophy, and radiation therapy. The peak incidence is during the adolescent growth spurt, boys between 12 and 16 years of age (mean, 13.5 years) and girls between 10 and 14 years of age (mean, 11.5 years). The age at diagnosis decreases with increasing obesity. Most children with SCFE have delayed skeletal maturation. SCFE is bilateral in up to 80% of cases, although 30% to 40% of these cases are asymptomatic and discovered only on screening radiographs. In unilateral cases, the left hip is affected twice as often as the right.

Although SCFE is associated with endocrine disorders, renal osteodystrophy, and radiation therapy, most cases are idiopathic and associated with obesity. The cause of SCFE is unknown but is likely to be related to biomechanical and hormonal factors. Obesity results in increased shear forces across a more vertically and posteriorly oriented growth plate that has been weakened by architectural irregularities and hormonal changes of puberty. The consequence is slippage of the epiphysis inferiorly and posteriorly in the direction of the weight-bearing force.

Classification of SCFE is based on stability. With or without crutches, in stable SCFE, ambulation is possible, whereas in unstable SCFE, ambulation is not possible. This classification system is preferred to the traditional classification because it does not rely on patient or parent recall for duration of symptoms and provides information about prognosis.

Approximately 90% of all cases of SCFE are stable, and children present with intermittent limp and pain for weeks to months. The pain of SCFE may be localized to the hip, thigh, groin, or knee. Atypical manifestations of SCFE include weakness and easy fatigability of the affected limb and limping on exertion. With continued slippage, there is progressive external rotation and shortening of the involved extremity, with subsequent difficulty in daily activities, such as tying shoes. On examination, children initially have a slight loss of internal rotation and experience pain only at the extremes of motion. As the slip becomes more severe, the gait becomes more antalgic, internal rotation is lost, abduction and flexion of the hip increase, thigh and gluteal muscle atrophy is more pronounced, and leg-length discrepancy develops.

Fig. 175.24. Crescent sign (subchondral lucent zone) in early Legg-Calvé-Perthes disease. (Courtesy Dr. Marianne Gausche-Hill.)
evaluate for slippage (Fig. 175.26). The modified Klein’s line is a comparison of the amount of epiphysis lateral to the Klein line on the symptomatic side compared with the same measurement on the asymptomatic side, with a difference of 2 mm being significant.13 Even with the modified Klein’s line, 13% of SCFEs were missed, highlighting the need for a lateral film.14 The blanch sign of Steele, another SCFE finding seen on the AP radiograph, is a crescent-shaped area of increased density in the proximal portion of the femoral neck created by superimposition of the posteriorly displaced epiphysis on the femoral neck.

As the slip continues, the femoral metaphysis is more laterally displaced from the medial wall of the acetabulum, and the epiphysis continues to be displaced inferiorly and posteriorly relative to the metaphysis. Over time, remodeling smooths away the superior and anterior portions of the femoral neck and, in an attempt to buttress the slippage, a callus is formed at the inferior and posterior portions of the femoral neck. Acute unstable slips will not show any bone healing or remodeling. MRI can be used to confirm epiphyseal displacement in patients who have symptoms but no radiographic findings suggestive of SCFE; findings include widening of the physis, bone marrow edema of the metaphysis, joint effusion, and synovitis.

Slip severity is described in either of two ways. The simplest classification describes the amount of displacement of the femoral head on the femoral neck. In mild SCFE, the amount of displacement of the femoral head is less than one-third, in moderate SCFE, between one-third and one-half and, in severe SCFE, the femoral head is displaced more than half the width of the femoral neck. A more accurate description of the magnitude of slippage is obtained by measurement of the epiphyseal shaft angle of Southwick (Fig. 175.27). On a frog leg lateral radiograph of the pelvis, a line is drawn between the anterior and posterior tips of the epiphysis at the physeal plate level. A second line is then drawn perpendicular to the epiphyseal line. Next, a line is drawn along the midshaft of the femur. The epiphyseal shaft angle is formed by the intersection of the perpendicular and femoral shaft lines. The magnitude of slip displacement is the angle of the involved hip.
Specific Disorders

Apophyseal Injuries

Principles

The apophysis is a cartilaginous structure that serves as a site for insertion of tendons on the growing bone. It has its own growth plate, with a slower rate of growth than the nearby epiphyseal plate. Apophysis is unique to patients with skeletal immaturity and involves inflammation of this actively growing bone prominence, which is under great tensile stress. Apophyseal injuries are secondary to a single episode of macrotrauma or may follow repetitive microtrauma. Common apophyseal injuries include medial epicondylitis, Osgood-Schlatter syndrome, and Sever’s disease.

Specific Disorders

Osgood-Schlatter Syndrome. In 1903, Osgood and Schlatter independently reported traumatically induced apophyseal injury to the tibial tubercle in adolescents. This entity, now known as Osgood-Schlatter syndrome, is the most common of the apophyseal disorders. It is most common in boys between 10 and 15 years and in girls between 8 and 13 years. It is bilateral in up to 30% of patients.

Children with Osgood-Schlatter syndrome have tenderness, pain, and swelling at the site of insertion of the patellar tendon on the tibial tubercle. The tibial tubercle may be prominent and the quadriceps tight. Pain is worsened with activities that cause the quadriceps to contract and stress the tibial tubercle, such as running and jumping. Extension of the knee against resistance causes pain, but resisted straight leg raises are painless. Osgood-Schlatter syndrome is a clinical diagnosis, and radiographs are not indicated. If radiographs are obtained, lateral views of the tibial tubercle may appear normal or may show an enlarged, fragmented, and irregular tibial tuberosity, with or without an overlying bony ossicle. These findings are nonspecific and are not diagnostic on their own. Ultrasonography may reveal pretilial swelling, fragmentation of the ossification center, insertional thickening of the patellar tendon, and/or excessive fluid collection in the infrapatellar bursa.

Treatment of Osgood-Schlatter syndrome includes ice and modification of activity, with or without NSAIDs. The use of a patellar strap may help relieve symptoms. After the acute inflammatory process has resolved, treatment focuses on strengthening and stretching of the quadriceps muscles. Mild pain during activity is permissible. With more severe symptoms, the risk of avulsion of the tibial tubercle should be weighed against the benefits of competing. In rare cases, conservative therapy is insufficient, and a 2- to 3-week trial of crutches is appropriate. Steroid injections are not recommended due to the risk of patellar tendon rupture. Complete recovery without residual pain or weakness is typical. Recovery usually occurs within weeks but, in some cases, may not be complete until the underlying growth plate has closed.

Sever’s Disease. Sever’s disease is an apophysis of the calcaneus due to traction by the gastrocnemius-soleus complex. It was initially described in 1912 and manifests as posterior heel pain in an 8- to 13-year-old athlete. It is bilateral in 60% of cases. As with other apophyseal injuries, pain is exacerbated by activity. Sever’s disease can be associated with growth or tight heel cords. Impact sports, especially those that involve running, and sports in which cleats are worn are implicated in the development of Sever’s disease.

Patients have pain at the insertion site of the Achilles tendon and plantar fascia on the calcaneus. Tenderness is elicited when the calcaneus is squeezed bilaterally. Dorsiflexion of the ankle is restricted by tight heel cords. Radiographs may be normal in appearance or may show partial fragmentation and increased density of the calcaneal apophysis, although these findings can be normal.

Treatment of Sever’s disease consists of ice, massage, stretching of the plantar fascia and involved muscles (gastrocnemius-soleus complex and ankle invertors and evertors), NSAIDs, and shock-absorbing shoe inserts. Heel cups can be beneficial if their use is accompanied by stretching to avoid exacerbation of the calf muscle contracture. Patients in whom conservative management fails should be evaluated for calcaneal stress fractures. Modification of activity and a trial of crutches for 3 to 4 weeks may be necessary.

Little League Elbow. Little League elbow is a term used to describe a group of injuries of the elbow, including apophysitis, medial epicondylitis, and osteochondritis dissecans of the radial head and capitellum. The injury involves an overuse phenomenon resulting in inflammation at the origin of the forearm flexors. It generally affects overhand athletes, including baseball pitchers and tennis players, most commonly preadolescents. Examination reveals localized tenderness and swelling over the medial epicondyle and pain with resisted flexion of the wrist. There may be a slight flexion contracture. Radiographs may be normal in appearance or may show fragmentation, sclerosis, and widening of the medial epicondylar apophysis. Treatment consists of ice, NSAIDs, and modification of activity. Throwing is restricted until the symptoms have resolved. After resolution of the pain, the patient can begin a program of muscle stretching and strengthening, with a gradual return to throwing. Recovery usually takes 4 to 6 weeks. Patients with persistent pain, locking or decreased range of motion of the joint, or lateral elbow pain should be evaluated for avulsion fractures, loose bodies, and osteochondritis dissecans.

Apophyseal Injuries of the Hip

Apophyseal injuries of the hip occur where major abdominal and hip muscles originate or insert, such as the anterior superior iliac spine, anterior inferior iliac spine, iliac crests, and ischial tuberosities. Dancers and distance runners are most commonly affected. Patients experience dull pain near the hip that is related to activity. Treatment includes strengthening and stretching of the abdominal and hip muscles and restriction of activity.
**Avulsion Fractures.** Any patient with sudden onset of apophyseal pain after an acute traumatic event should be evaluated for an avulsion fracture of the apophysis or adjacent bone. Such fractures occur when the muscle attachments to the apophyses are pulled off during strong active contractions against resistance. Examination will reveal localized tenderness and swelling. Plain films are usually diagnostic (Fig. 175.28). Ultrasonography may play a role when the diagnosis is in question. Findings include a hypoechoicogenic zone, increased distance to the apophysis, dislocation of the apophysis, and mobility of the apophysis on dynamic examination. Treatment of an avulsion fracture is based on the degree of separation; displacement less than 2 cm with a hip avulsion and less than 5 mm with a medial epicondyle avulsion can be immobilized for 4 to 6 weeks, with subsequent slow resumption of activities. Widely separated avulsion fractures are treated surgically.

![](Fig. 175.28. Avulsion of the inferior iliac spine in a child with hip pain after kicking a soccer ball. (Courtesy Dr. Marianne Gausche-Hill.))

**KEY CONCEPTS**

- The growth plate is the weakest part of the bone and is more likely to separate before the adjacent tendon or ligament tears, thereby making sprains uncommon.
- Of supracondylar fractures, 95% are of the extension type. Displaced fractures are at risk for neurovascular injury and compartment syndrome; the anterior interosseous branch of the median nerve and the brachial artery are most commonly involved.
- Developmental dysplasia of the hip affects 1% of children; all children who are not yet walking should have a thorough hip evaluation, including Ortolani and Barlow testing.
- Transient synovitis presents between 3 and 9 years of age and usually involves the hip. It can be differentiated from septic arthritis and other causes of hip pain with a thorough physical examination and directed laboratory and radiographic evaluation.
- The peak incidence of septic arthritis is between 6 and 24 months of age. Patients present with pain, fever, and decreased use of the involved limb. The knee is usually involved, followed by the hip. Inflammatory markers tend to be elevated, although they may be normal in young children with *Kingella kingae* infection. Blood and synovial fluid cultures are positive less than 50% of the time. *Staphylococcus aureus* is a frequent culprit. Treatment consists of joint drainage and empirical antibiotics (eg, nafcillin and ceftriaxone, with or without vancomycin).
- Examination of the hip is warranted in all patients with knee pain.
- Legg-Calvé-Perthes disease is an idiopathic avascular necrosis of the hip that has a peak presentation between 5 and 7 years of age. It is bilateral in 20% of cases.
- A slipped capital femoral epiphysis (SCFE) is a posteroinferior slippage of the proximal femoral epiphysis on the metaphysis. It is more common in boys than girls, more common with obesity, and bilateral in 80% of cases. It is best seen on a cross-table or frog leg lateral view radiograph; 90% are stable.
- Osgood-Schlatter disease is the most common form of apophysitis. The onset is insidious, and treatment is conservative and symptomatic. A sudden onset of apophyseal pain is more suggestive of an avulsion fracture.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

**CHAPTER 175: QUESTIONS & ANSWERS**

**175.1.** A 7-year-old boy presents with left elbow pain following a fall. He has a moderately swollen left elbow and holds his elbow in extension. He has pain and crepitus at the elbow after his fall, he has refused to walk or put weight on his left leg but is able to crawl without difficulty. Anteroposterior radiographs may reveal the injury. Which of the following statements regarding this patient’s most likely injury is true?

A. An anterior fat pad may be normal.

B. An elbow flexion mechanism is likely.

C. Brachial artery injuries occur in less than one-third of cases.

D. The external epicondyle should be ossified on a radiograph.

E. The most commonly injured nerve is the radial nerve.

**Answer:** A. Supacdylyl humerus fractures involve an extension mechanism 95% of the time. On plain films, an anterior fat pad may be normal as long as it is not bulging or sail-shaped. A posterior fat pad is never normal and warrants further imaging. The CRITOE mnemonic is useful to recollect that the external (lateral) epicondyle is the last elbow ossification center to ossify (age 11 years). Neurovascular injuries are common, with brachial artery injuries in up to 40% of cases. The median nerve is most commonly injured.

**175.2.** Which of the following statements regarding nursemaid’s elbow true is true?

A. After reduction, normal use should be observed by 4 to 6 hours.

B. Peak incidence is between 6 and 8 years of age.

C. Pronation is the reduction technique of choice.

D. Radiographs are necessary before reduction.

E. Swelling and ecchymosis are common.

**Answer:** C. Pronation is associated with success rates equal to those for supination and is associated with less pain. Normal use should be observed within approximately 10 to 30 minutes. Radiography is not indicated unless there is swelling, erythema, ecchymosis, or deformity. The peak incidence is age 2 or 3 years, with a slight female predominance.

**175.3.** A 21-month-old presents after a fall from standing. Since the fall, he has refused to walk or put weight on his left leg but is able to crawl without difficulty. Anteroposterior (AP) and lateral views of the left lower extremity are normal. Which of the following statements regarding this patient’s most likely injury is true?

A. If not seen on routine radiographs, internal oblique radiographs may reveal the injury.

B. It requires a high-energy mechanism of injury.

C. Noaccidental trauma should be considered in all children with this injury.

D. Peak incidence is between 6 and 8 months of age.

E. Treatment consists of a below-knee walking cast and immobilization.

**Answer:** A. Toddler’s fractures are oblique nondisplaced fractures caused by low-energy torsional forces applied to the porous bone of infants and young children. The peak age of presentation is
between 9 and 36 months of age. The mechanism of injury can be as mild as the child's twisting on the leg while walking or a fall from an insignificant height. AP and lateral radiographs may reveal a spiral or oblique fracture extending downward and medi ally through the distal third of the tibia. An internal oblique radiograph is helpful if evidence of fracture is absent on the AP or lateral view. Treatment of a toddler's fracture consists of a long leg cast for approximately 3 weeks.

175.4. A 14-year-old obese male presents with progressively worsening left knee pain. On examination, he has full range of motion of the knee but is unable to move his left hip due to severe pain and is unable to bear weight. This patient's most likely injury would cause which of the following findings on routine radiographs?
A. Fragmentation of the femoral head
B. Inferiorly and posteriorly displaced femoral epiphysis relative to the metaphysis on a cross-table lateral view of the hip
C. Inferiorly and posteriorly displaced femoral epiphysis relative to the metaphysis on a frog leg view of the hip
D. Medial joint space widening on hip or pelvis radiographs

Answer: B. This patient's history is consistent with an unstable slipped capital femoral epiphysis (SCFE). The diagnosis of SCFE is made with AP and lateral radiographs of both hips. With stable slippage, AP and frog leg lateral pelvic radiographs should be obtained. When an unstable slip or a minimal slip is suspected, a cross-table radiograph replaces the frog leg lateral view. Fragmentation of the femoral head is seen in Legg-Calve-Perthes disease. Widening of the medial joint space is suggestive of a joint effusion and can be seen in Legg-Calve-Perthes disease, transient synovitis, or septic arthritis.

175.5. Which of the following statements regarding apophysial disorders is true?
A. The age of onset tends to be younger in females than in males.
B. The first-line treatment is casting and immobilization.
C. They are extremely rare.
D. They only occur in mature skeletons.
E. They usually occur in adolescents older than 16 years old.

Answer: A. Apophysitis is unique to patients with skeletal immaturity and involves inflammation of the cartilaginous structure that serves as a site for insertion of tendons on the growing bone. Growth contributes to the development of apophysitis; females mature at a younger age than males and are affected earlier in life. Apophysitis is common and is estimated to occur in 18% of pediatric patients. Children between 8 and 15 years of age are most frequently affected, with different apophyseal centers affected at different ages.
CHAPTER 176

Drug Therapy for the Pediatric Patient

Maryann Mazer-Amirshahi | Matthew D. Wilson

PRINCIPLES

Background

Emergency clinicians are tasked with treating not only a wide age range of pediatric patients but also a wide spectrum of disease. Nearly 75% of visits are associated with some form of pharmacotherapy during the visit or in the form of a prescription at discharge. Children may present to the emergency department (ED) with an acute-life threatening illness or injury. Although many children presenting for emergency care are otherwise healthy, children with complex medical needs and chronic illness account for a major portion of ED encounters. This is further complicated by the fact that despite significant need for appropriate pharmacotherapy for pediatric ED patients, there is a relative paucity of data regarding the safe and effective use of medications in this population.

Historical Perspective

The sulfanilamide disaster of the 1930s resulted in the deaths of several children and led to the passage of the Food, Drug, and Cosmetic Act of 1938; however, significant disparities in pediatric pharmacotherapy were largely precipitated by the thalidomide disaster of the 1960s. Thalidomide was widely marketed outside the United States as an antiemetic for pregnant women suffering from morning sickness until severe teratogenic effects, such as phocomelia, were discovered. Lessons learned from experience with the sulfanilamide and thalidomide disasters were fewer and took longer than their adult counterparts. In 1997, the FDA Modernization Act was passed, which essentially excluded children and women of childbearing age from clinical trials. This resulted in a general lack of clinical pharmacology data in the pediatric population, drug labeling that often advised against the use of many medications in children due to insufficient data, and high rates of off-label prescribing.

Recent Legislative Efforts

It had long been recognized that children had essentially become so-called therapeutic orphans, but it was not until the mid-1990s that legislative efforts began to focus on correcting this disparity. The US Food and Drug Administration (FDA) Pediatric Labeling Rule, passed in 1994 and promulgated in 1998, allowed for pediatric labeling based on the extrapolation of adult data if the course of disease was similar in both populations. In 1997, the FDA Modernization Act was passed, which provided for an extension of market exclusivity for manufacturers that performed pediatric clinical trials. A major stride toward therapeutic equity was made when the Best Pharmaceuticals for Children Act (BPCA) was passed in 2002. The goal of the BPCA was to promote clinical trials of pharmaceuticals in children that would generate safety and efficacy data, leading to more pediatric drug approvals and expanded labeling. This was followed by the Pediatric Research Equity Act (PREA) in 2003. PREA mandated that manufacturers conduct clinical trials in children for drugs under development that have the potential for pediatric use and expanded existing labeling for drugs that were already commonly used in children. Further progress was made in 2012 with the passage of FDA Safety and Innovation Act (FDASIA), which permanently reauthorized the BPCA and PREA. In addition, the FDASIA strengthened FDA authority over pediatric clinical trials and promoted studies in underserved populations, specifically neonates. Although progress in encouraging pediatric drug research has been gradual, the eventual increase in governmental regulation and engagement of manufacturers is shown in Table 176.1, which summarizes the significant legislation affecting research in pediatric pharmacology.

Current Landscape

This legislation has resulted in significant advances in pediatric pharmacotherapy, with over 500 drugs with new or expanded pediatric labeling as of late 2014. At the same time, there is still a lack of high-quality pediatric data for many drugs currently on the market and high rates of off-label use of therapeutics in children continue. In addition, labeling information for children was lacking in the package inserts for over 70% of newly approved pharmaceuticals over the past decade, and pediatric labeling revisions were fewer and took longer than their adult counterparts. Even when there are adequate pediatric data for a particular drug, there may not be a specific formulation suitable for pediatric use. There are several reasons that therapeutic equity continues to elude the pediatric population, including ethical and practical considerations when performing pediatric trials, pharmaceutical market factors, and limitations to current legislation. Ultimately, a multifaceted approach engaging stakeholders from industry, government, health care systems and clinicians, and patient advocacy groups will be required to ensure safe and effective pharmaceuticals for children.

PHARMACOKINETIC CONSIDERATIONS IN CHILDREN

Absorption

Physiologic differences in children can affect drug absorption, particularly for enteral administration, the major route of administration in children. However, these effects are rarely clinically significant in the ED. Fig. 176.1 illustrates many of the key factors that account for pharmacokinetic differences between children and adults. For example, in gastric absorption, young children have higher gastric pH levels, which affect the bioavailability of acid-labile drugs, and they have decreased gastric emptying times, which prolongs exposure to medications before they pass the pylorus. Variations in the intestinal tract also result in pharmacokinetic differences. The activity of drug-metabolizing enzymes on the intestinal border vary as development occurs, and differences in gut flora can affect drug absorption in young infants. One commonality between children and adults is that drug absorption is often impaired in the setting of critical illness.
Absorption of drugs via a non–oral route can vary significantly in children compared to adults. The topical route can result in increased absorption in children due to their relatively larger body surface area. Additionally, children's skin contains more water and has a thinner stratum corneum. These factors make children more prone to systemic toxicity from dermally applied drugs. Intramuscular administration of medication is less common in young children because absorption is erratic; however, over time, drug absorption becomes more efficient via this route in older children. Absorption of rectally administered medications also varies widely, depending on the age of the child and chemistry of the drug involved. However, this route can be used for medications when children are unable to tolerate or are refusing oral administration, such as for the antipyretic acetaminophen and the antiepileptic diazepam. The ability to administer medications via the pulmonary route is particularly desirable in pediatric populations, given the high prevalence of respiratory conditions, such as reactive airway disease. At the same time, children are less able to coordinate the use of a metered-dose inhaler to deliver these medications properly; parental assistance and adjunct devices such as spacers should be used to maximize efficacy by minimizing drug deposition in the oropharynx.

Distribution

Distribution of drugs can differ significantly in children, which has important clinical implications. For example, neonates and infants have higher total body water and larger volumes of distribution; therefore, dosing of medications such as aminoglycosides will differ in this age group, and drug concentrations should be closely monitored. Free drug concentrations are also affected by the relatively lower concentrations of plasma proteins in infants and young children. A consideration specific to neonates is the displacement of bilirubin from protein-binding sites by drugs such as ceftriaxone, which can lead to kernicterus. Consequently, these medications should be avoided until the blood-brain barrier matures. Table 176.2 presents examples of other commonly used medications in the practice of emergency medicine that carry pediatric-specific toxicities as a result of pharmacokinetic and other idiosyncratic differences.

Childhood obesity has reached epidemic proportions in the United States and worldwide, resulting in more children being placed on medications for chronic conditions, such as antihypertensives. Because these medications have been traditionally prescribed for adults, there is a significant paucity of safety and efficacy data in children, which could predispose them to adverse drug events. Increased body fat content can alter the distribution

TABLE 176.2  Examples of Commonly Used Medications with Pediatric-Specific Toxicities
of lipophilic drugs, leading to the accumulation of these medications and potentially resulting in adverse effects. At the same time, there is a lack of guidelines for appropriate dosing of most medications in obese adults, let alone in the pediatric population.17

Metabolism

Drug metabolism in neonates and infants is diminished because of immature drug-metabolizing enzymes. Lower or less frequent dosing may be required to prevent toxicity in this age group. An example of toxicity due to differences in drug-metabolizing enzymes is the neonatal gasping syndrome. Benzyl alcohol, a common preservative for parenteral medications, is metabolized to benzoic acid, which is detoxified by glycine conjugation. Glycine conjugation is decreased in neonates and benzoic acid accumulates, leading to metabolic acidosis, respiratory distress, and cardiovascuar collapse. Between the ages of 1 and 6 years, children may have increased drug-metabolizing activity compared to adults and may require higher relative doses. As children approach adolescence, drug metabolism is generally the same as in adults.

Elimination

The kidney is the primary route of elimination for many parent compounds and active metabolites. In the neonate and infant, glomerular filtration is decreased for the first 6 months of life, and tubular secretion is decreased for the first year. To avoid toxicity, maintenance doses should be decreased or dosing intervals extended. An important example in the ED is gentamicin, where it has been demonstrated that using dosing regimens designed for older children and adults has resulted in significant toxicity.15

OTHER CONSIDERATIONS

Drug Therapy in the Neonate

Neonates are the subgroup of pediatric patients that differ the most with regard to physiology and drug disposition; however, there is also the greatest paucity of pharmacologic data in this population.12 Emergency clinicians caring for neonates should consult drug references for specific prescribing information because dosing recommendations, administration, and contraindications differ in this age group. Early consultation with a neonatologist may be warranted, depending on the clinical scenario.

Neonates can also be exposed to and experience subsequent toxicity from pharmaceuticals via lactation. For example, the postpartum use of codeine in lactating mothers has been associated with toxicity in the newborn. This phenomenon has been linked to maternal CYP2D6 polymorphisms, which result in ultrarapid metabolism of codeine to morphine. High concentrations of morphine are excreted in the breast milk, which can cause toxicity in the infant. Although many medications are safely administered during breast-feeding, this underscores the importance of obtaining a complete maternal medication history when evaluating a breast-fed infant, as well as consulting a lactation reference when prescribing medications to nursing mothers. This can be difficult because there are limited human data regarding medication use in pregnancy, and multiple factors need to be considered, including maternal comorbidities, therapeutic alternatives, and the benefits of continued breast-feeding, when possible.18

Use of Antipyretics in Children

Fever is one of the most common presenting complaints for pediatric ED and urgent care visits. Fever is a common physiologic response to illness, which is rarely harmful, and likely serves a beneficial role as part of the immune response. At the same time, many parents and clinicians still aggressively treat even slight elevations in temperature with antipyretics. This practice has not been proven to be beneficial and may even be harmful, because therapeutic errors while administering antipyretics are common.19 One study has demonstrated that parents administer antipyretics incorrectly up to 50% of the time, which can lead to overdose and subsequent toxicity. Recently, manufacturers have moved to one standardized concentration of acetaminophen for infants and children in an effort to prevent dosing errors.

Current recommendations focus on maintaining patient comfort and not normalizing temperature. When dosed appropriately, acetaminophen and ibuprofen are equally effective for the management of fever.19 Ibuprofen should be avoided in infants younger than 6 months because of pharmacokinetic differences and ongoing renal development in this age group. Combined regimens or alternating therapy with acetaminophen and ibuprofen may be slightly more effective; however, this approach is also more complicated and may predispose to medication errors, with little clinical benefit.19 Emergency clinicians should focus on patient comfort when prescribing antipyretics in the ED and counsel parents regarding the safe and appropriate use of these medications on discharge. Table 176.3 presents manufacturer-recommended dosing for commonly used antipyretics and analgesics; Box 176.1 provides counseling points for parents regarding fever and antipyretic use.

OVER THE-COUNTER COUGH AND COLD MEDICATIONS

Cough and cold symptoms are complaints commonly encountered in pediatric ED patients. Until recently, over-the-counter (OTC) cough and cold medications containing various combinations of antitussives, antihistamines, decongestants, expectorants, and antipyretics were in widespread use for symptomatic relief in children. In 2007, a series of initiatives was launched to curb the use of these medications in young children due to a lack of efficacy data and mounting safety concerns, including therapeutic errors, unintentional ingestions, and adverse drug effects.
In October 2007, a joint panel meeting of the FDA’s Nonprescription Drugs and Pediatric Advisory Committees convened to advise against the use of OTC cough and cold medications in children younger than 6 years. Later that month, the Consumer Healthcare Products Association (CHPA) issued a position statement and voluntarily withdrew OTC cough and cold products marketed for use in children younger than 2 years. In January 2008, the FDA formally recommended against the use of OTC cough and cold medicines in children younger than 2 years. The CHPA subsequently issued additional warnings against the use of these medications by children younger than 4 years. Currently, the American Academy of Pediatrics (AAP) advises against the use of OTC cough and cold medications in children younger than 6 years, and the FDA continues to review available data in consideration of changing the labeling for OTC cough and cold medications for all children aged 2 to 6 years.

Since these initial labeling changes were instituted, there has been a decrease in therapeutic errors and unintentional ingestions of OTC cough and cold medications reported to US poison centers. In addition, there was a decrease in ED visits, health care utilization, and fewer severe and fatal adverse medical outcomes. At the same time, to date, these initiatives have not resulted in a significant decrease in the use of OTC cough and cold medications in pediatric ED patients; however, there has been an overall decrease in prescription cough and cold medication use in this age group. Emergency clinicians should be cognizant of current recommendations to avoid these medications in young children and educate parents regarding the dangers of OTC cough and cold medications, also keeping in mind that mind prescription cough and cold alternatives have similar safety and efficacy concerns. Parents should also be counseled regarding alternative therapies, such as nasal suctioning, honey in children older than 1 year, and use of a humidifier.

### Phenothazines

Phenothiazine medications such as promethazine were frequently used in pediatric patients, primarily in cough and cold preparations, for sedation, and as antiemetics. Since promethazine was approved in the early 1950s, there have been multiple cases of respiratory depression, apnea, and death in children. Due to these mounting safety concerns, the AAP has recommended against the use of phenothiazines for sedation in children. In 2000, the FDA also issued similar warnings, but continued reports of pediatric toxicity prompted the addition of a formal black box warning recommending against the use of promethazine in children younger than 2 years in 2004. In 2009, another black box warning was added, highlighting the risks of inappropriate parental use of promethazine resulting in severe tissue necrosis. Since these recommendations, the use of phenothiazines for sedation and vomiting and as an antihistamine has declined, likely as a result of warnings and increased availability of safer therapeutic alternatives.

### Opioid Analgesics

Pain in pediatric ED patients has been historically poorly assessed and undertreated. Over the past 2 decades, there has been an emphasis on the identification and treatment of pain, and opioid analgesic use in pediatric ED patients has increased substantially. Opioid analogesics can be used safely and effectively in children for the management of moderate to severe pain in the ED and should not be withheld when indicated. At the same time, there are safety concerns regarding the use of opioid analgesics in pediatric patients of which emergency clinicians should be cognizant to minimize the potential of adverse drug events.

The toxicity of codeine in breast-fed infants whose mothers are CYP2D6 ultrarapid metabolizers has been discussed previously. Toxicity, including death, has also been documented in children who received codeine after a tonsillectomy and/or adenoidectomy for postoperative pain management. Children who are predisposed to codeine toxicity include those with obstructive sleep

**Counseling Tips for Parents and Caregivers for Safe Antipyretic Use**

- Fever is a clinical sign that the body may be fighting infection and children should be monitored for signs of serious illness.
- Be sure the child maintains adequate hydration during febrile illness.
- Antipyretics should be given to minimize discomfort; maintaining a normal body temperature is less important.
- The use of combination products and alternating use of antipyretics can lead to dosing errors and therapeutic duplication.
- Do not use ibuprofen in children younger than 6 months.
- Do not use aspirin in children younger than 15 years due to the risk of Reye’s syndrome.
- Counsel caregivers and parents regarding appropriate weight-based dosing for the child.
- Recommend use of a calibrated measuring device to avoid dosing errors.
- Store antipyretics and all medications out of the reach of children.
- Do not use isopropyl or ethyl alcohol to cool the skin because it may result in toxicity from topical absorption.
In 2013, a black box warning was added to the labeling of codeine products contraindicating the use of codeine for postoperative pain in pediatric patients who have undergone tonsillectomy and/or adenoidectomy. It is unclear how this risk translates to the pediatric ED population. With regard to codeine use for other painful conditions, it is recommended that emergency clinicians only use codeine if the anticipated benefits outweigh the risk. The FDA continues to review safety data pertaining to codeine use in children.37

In recent years, there has been a dramatic increase in the use of opioid analgesics that has been paralleled by rising rates of misuse, abuse, and related-fatalities.35,36 This phenomenon is not isolated to adult patients. There has been a significant rise in opioid analgesic use in pediatric ambulatory care and ED patients, with the greatest increases in use seen in adolescent patients. The most common medications prescribed for adolescent ED patients are hydrocodone and oxycodone products, which are also commonly abused for nonmedical purposes.33

There have been profound increases in nonmedical use and subsequent morbidity and mortality related to these agents among adolescents and young adults. This may be due to the fact that adolescents may be more likely to engage in risk-taking behavior, and opioid analgesics have become easier to obtain.39 One study found that nearly 13% of high school seniors reported nonmedical use of a prescription opioid.39 Prescription opioids are the second most commonly abused substance by adolescents in the United States, surpassed only by marijuana.40 Additionally, up to 80% of nonmedical users obtained the drug from a previous medical prescription or from a relative or friend.40 Increased availability of prescription opioids to adolescents has led to overdoses, medical complications, and long-term addiction.42 Even more disturbing is the fact that opioid-related fatalities in adolescents have more than doubled in the past 25 years.33

It is important for emergency clinicians to balance adequate analgesia with the risks associated with the use of prescription opioids. Clinicians should determine whether an opioid is indicated, guided by evidence-based practice guidelines whenever possible. Nonopioid alternatives (eg, nonsteroidal antiinflammatory drugs) should be used as primary therapy or as an adjunct to minimize the dose of opioids. When an opioid is clearly indicated, it is important for clinicians to follow institution-based protocols for dosage and administration to avoid adverse drug events. Additionally, it is recommended that clinicians follow safe prescribing practices for opioid analgesics, as presented in Box 176.2, particularly for adolescent patients.44,45

### Mediation Safety and Adverse Drug Events

Children are not only at an increased risk of medication-related injury—some have estimated up to threefold the inpatient risk of adults—for pharmacokinetic reasons but are also susceptible to other contributing risk factors. Because of the aforementioned legislative restrictions in pediatric drug research, many medications are used off label, with dosing based on experience and susceptible to error. Even when a medication has pediatric data shown in the drug labeling, this information is often not clearly presented and may offer little guidance to the prescriber. For example, the age range for which a medication is formally approved is often not listed in the indications section of the labeling. Approved pediatric-specific dosing information, when

**Best Practices for Prescribing Opioid Analgesics in the Emergency Department**

- Assess if there is an indication for an opioid analgesic; nonopioid therapies should be optimized and used as adjuncts, whenever possible.
- Perform a risk assessment for nonmedical use, particularly in adolescent patients.
- Consult state prescription drug monitoring programs and prior medical and pharmacy records if there is concern for nonmedical use.
- Short-acting opioids are preferred versus extended-release formulations.
- Use caution when combining opioid analgesics with other central nervous system depressants, such as benzodiazepines.
- Limit the duration of therapy to avoid having leftover doses.
- Provide instructions for the safe disposal of any unused medication.
- Arrange for close outpatient follow-up.
- Counsel parents and caregivers regarding signs of prescription drug abuse.
is a significant lag time between when a specific toxicity is noted. The references for this chapter can be found online by accessing the accompanying Expert Consult website.

Pediatric-focused studies are commonly found in yet another section, under special populations. The lack of pediatric-specific formulations is also a contributor to adverse drug events and poor patient adherence. This is further complicated by the fact that there is little financial incentive for manufacturers to develop pediatric-specific formulations. Because pediatric formulations are not available for many medications, parents and clinicians may have to split fixed-dose adult tablets, or liquid formulations may need to be extemporaneously compounded, which introduces the potential for therapeutic errors. In addition, the poor palatability of adult formulations can lead to noncompliance; oral solutions, suspensions, and rapidly disintegrating and chewable tablets are preferred. Parents should be counseled regarding proper measurement and administration of prescribed medications, and a dosing syringe should be provided.

There are other factors that contribute to adverse drug events in children. Weight-based dosing and calculations required for many pediatric medications can present an additional step particularly prone to error in the delivery of emergent medications. Also, formulas used to calculate pediatric dosing derived from adult reference values are often inaccurate. Medication reconciliation in pediatric patients is also often inaccurate, which can contribute to suboptimal therapy and adverse drug events. Parents and caregivers should be specifically asked about all prescription medications, OTC medications, homeopathic preparations, and dietary supplements. Details regarding dosage and schedule should also be obtained. Very young children are nonverbal and cannot communicate allergies or current medications. In addition, they are less able to verbalize adverse effects when they do occur. Even when adverse drug events are identified, they are often underreported. This is further complicated by the fact that there is a significant lag time between when a specific toxicity is noted and when labeling revisions occur.

Ongoing attempts to mitigate these risks include the use of clinical pharmacists in the ED, separation of pediatric and adult care locations, and increased use of human factors and information technology solutions. There are also well-demonstrated bedside dosing reference guides for emergency pediatric medications, such as the Broselow and Mercy tapes. The advent of hand-held wireless technology and gradual adoption of inpatient electronic health record (EHR) systems have generated many new reference options for pediatric pharmacology. It is thought that new decision support tools in the EHR system, such as computerized physician order entry, will help decrease adverse events, because many are related to weight-based dosing errors. Although calculation errors (eg, decimal point entry) still occur in computer-based systems, it is thought that decision support for infusions, maximum doses, and HER-linked medication reconciliation will contribute to a decrease in medication errors. At the same time, EHRs can also precipitate errors when clinicians “copy and paste” without critically evaluating data. The ultimate responsibility for medication dosing rests with the ordering clinician, dispensing pharmacist, and administering nurse. Table 176.5 presents a selection of different types of decision support tools that can serve as a reference to emergency clinicians.

In recent years, prescription drug shortages have emerged as a threat to public health. Drug shortages can lead to delayed treatment or no treatment when indicated. This is best exemplified during past influenza seasons, when there were critical shortages for the pediatric formulation of oseltamivir. Sometimes, alternative medications should be substituted that may be more toxic or less effective, and medication errors can occur when emergency clinicians are forced to use therapeutic alternatives with which they are less familiar. The reasons for the rising rates of prescription drug shortages are multifactorial, and it is anticipated that shortages will continue as a problem in the foreseeable future, despite mitigation efforts. Emergency clinicians should be cognizant of current drug shortages that may affect their practice and work to design protocols for the ethical distribution of available supplies of medications in short supply, as well as for safer use of therapeutic alternatives.

### KEY CONCEPTS

- Recent legislative efforts have begun to remove regulatory hurdles in closing the therapeutic gap between adult and pediatric patients.
- Awareness of differences in pediatric pharmacokinetics and specific drug toxicities is of critical significance for the safe and effective use of medications in children.
- Avoid prescription and OTC cough and cold medications in children younger than 6 years because these agents have limited efficacy data and may cause harm.
- Counsel parents about the management of fever and appropriate indications for and proper use of antipyretics.
- Perform a risk assessment prior to prescribing opioid analgesics and, when indicated, use safe prescribing practices and monitor for signs of prescription drug abuse.
- A multifaceted approach using clinical support systems and readily available reference tools are essential for the delivery of optimal emergent pediatric care.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
REFERENCES

19. Fein JA, Zempsky WT, Craven JP, et al: Relief of pain and anxiety in pediatric patients during the emergency department (ED) for arm pain with an old thumb spica splint and states that she ran out of her oxycodone prescription for a possible fracture and has been unable to follow-up with her orthopedist. Vital signs, examination, and radiographs are unremarkable. Which of the following is a best practice option for ED opioid prescribing?

A. Avoiding confusion by minimizing adjunct medication options

B. Consulting state prescription drug monitoring programs and prior medical and pharmacy records
C. Encouraging the parents of adolescents to maintain a central location in the house to store old and unused prescriptions
D. Working independently of outpatient providers to avoid undertreating chronic pain

Answer: B. Perform a risk assessment prior to prescribing opioid analgesics and, when indicated, use safe prescribing practices and monitor for signs of prescription drug abuse. Although parents should help with an adolescent’s medications, unused prescriptions should be properly disposed of instead of maintained in the household, where they will be susceptible to future unintended misuse. Chronic pain management requires a multifaceted approach with emergency providers who are aware of an individual’s pain management contract so as not to contribute to overuse. Adjunct medications such as nonsteroidal antiinflammatory drugs or neuroactive agents can help reduce overall opioid requirements. Prescription drug monitoring programs should be used, when possible, to limit the overprescribing of opioids from the emergency department.

176.2. Which of the following factors contributes to the relatively fewer number of pediatric-specific drugs and formulations compared to the adult population?
A. Ethical and institutional considerations of pediatric trials
B. FDA rules prohibiting extrapolation of adult data to pediatric labeling
C. Inability to use drugs approved for adults that are off label for children
D. Lack of federal mandate that manufacturers conduct clinical trials in children for drugs under development that have the potential for pediatric use

Answer: A. Recent legislative efforts have begun to remove regulatory hurdles in closing the therapeutic gap between adult and pediatric patients. The Pediatric Research Equity Act (PREA) in 2003 mandated that manufacturers conduct clinical trials in children for drugs under development that have the potential for pediatric use. The FDA Pediatric Labeling Rule in 1994 allowed for pediatric labeling based on extrapolation of adult data if the course of disease was similar in both populations. There are high rates of off-label use for many drugs used in children. These federal regulations and more were put in place to encourage pediatric research, despite the ethical and institutional considerations of pediatric trials, which can prove more difficult to surmount than in the adult population.

176.3. A healthy, fully vaccinated 11-month old male infant presents to your department for evaluation of a fever of 38.4°C (101.1°F) this morning that responded to a dose of acetaminophen. The physical examination reveals a well-appearing, afebrile infant with clear lungs. The patient has an unremarkable evaluation and, during the discharge process, his parents ask for advice regarding fever management. Which of the following statements is correct?
A. Aspirin should not be used in children younger than 15 years because of the risk of Reye’s syndrome
B. Cool water baths and creams should be used to supplement antipyretics, even if they cause some discomfort to the patient.
C. Ibuprofen cannot be used in this age group because of ongoing renal development.
D. Over-the-counter (OTC) antipyretics are standardized, contain similar products and formulations, and are thus interchangeable.

Answer: A. Counsel parents and caregivers about the management of fever and appropriate indications for and proper use of antipyretics. There is no need to cause discomfort with external cooling methods for fever control. Ibuprofen should not be used in children younger than 6 months because of ongoing renal development. The formulations and dosing of OTC antipyretics are varied and cannot be used interchangeably. The correct answer is A because of the risk of Reye’s syndrome with aspirin administration during a viral illness in children younger than 15 years.

176.4. Which of the following statements regarding pediatric pharmacokinetics is correct?
A. A thinner stratum corneum and increased body surface area contribute to a greater risk for systemic toxicity from dermally administered drugs.
B. An immature blood-brain barrier can result in kernicterus after ceftriaxone administration in neonates, resulting in increased bilirubin production.
C. Because of minimal differences in the volume of distribution and renal development, weight-based dosing of gentamicin without attention to age is sufficient.
D. Quicker gastric emptying and decreased gastric pH in neonates increase systemic absorption of enterally administered medications.

Answer: A. Awareness of differences in pediatric pharmacokinetics and specific drug toxicities is of critical significance for the safe and effective use of medications in children. The dosing of gentamicin needs to account for age-based differences in renal development in addition to weight-based differences in distribution volume. Decreased gastric emptying times and an increased pH can prolong exposure to medications before they pass the pylorus. An immature blood-brain barrier can result in kernicterus from bilirubin displacement by ceftriaxone. The correct answer is that a thinner stratum corneum and increased body surface area contribute to a greater risk for systemic toxicity from dermally administered drugs.

176.5. Which of the following steps can be taken to reduce pediatric dosing errors?
A. Adoption of electronic health records to decrease weight-based dosing errors
B. Calculation of weight-based dosing for all emergent medications administered in code situations as opposed to using a validated quick reference guide
C. Limiting hospital pharmacist presence in the emergency department to avoid delays in bedside care
D. Medication reconciliation should occur with just the patient present to limit primary caregiver influence

Answer: A. A multifaceted approach using clinical support systems and readily available reference tools are essential for the delivery of optimal emergent pediatric care. Caregivers are an integral part of medication reconciliation. ED pharmacists have been proven to increase departmental accuracy in pediatric medication management. Validated quick reference guides for code drug administration have been shown to decrease errors and improve efficiency.
Child Abuse

Daniel Lindberg

Child maltreatment is an all-encompassing term that includes all forms of child abuse: physical abuse, sexual abuse, emotional abuse, child neglect (physical, emotional, educational), and medical child abuse (previously known as Munchausen syndrome by proxy).

PHYSICAL ABUSE

PRINCIPLES

Child physical abuse is a leading cause of death and disability for young children. In the United States, estimates suggest that more than 120,000 children are victims of physical abuse with more than 550 deaths each year, many of which are preventable. Physical abuse is also commonly missed—approximately 30% of abusive head trauma and 20% of abusive fractures are missed on initial presentation. Abuse is especially difficult to identify, because it is overwhelmingly a problem that affects pre-verbal children, particularly infants younger than 6 months old. Not surprisingly, caregivers frequently omit or obscure the true history. Key portions of the physical examination (eg, neurological and musculoskeletal examinations) are limited; early recognition of abuse often depends on identifying subtle, minor, or self-limited injuries. With these challenges, current practices are highly variable, and children are frequently returned to abusive environments. Current practice also shows signs of reporting bias; testing and reporting for abuse are disproportionately high for African-American and poor families, whereas missed abuse is higher for affluent or white families.

Overcoming these challenges is essential for abused children and their families. Because violence is a disease that affects entire households, recognition of abuse is important for not only for the children themselves but also for siblings and parents. For abuse survivors and those who share a violent household, the long-term health effects of toxic stress are severe, diverse, and widespread.

Role of the Emergency Clinician

It is rarely possible and almost never necessary to definitively diagnose abuse in the emergency department (ED). Care of abused children requires the cooperation of medical, social, and law-enforcement agencies over weeks and months. Emergency clinicians are responsible for raising the initial concern for abuse and working with other professionals, including general pediatricians, child protective services (CPS) agencies, and child abuse pediatricians to stratify the risk for abuse and to arrange for ongoing care.

Inevitably, some children who are evaluated for abuse will ultimately be determined to have an innocent explanation for their injuries. Most injuries in childhood are not the result of abuse, and unusual events may produce unusual or unusually severe injuries. To facilitate the evaluation and to preserve the doctor-patient relationship, emergency clinicians should maintain a routine and standardized approach to abuse evaluations. Non-accusatory statements can explain the need for testing while minimizing conflict (Box 177.1).

CLINICAL FEATURES

Social and Demographic Risk Factors

Although social and demographic risk factors (eg, poverty, intimate partner violence, substance use, and the presence of an unrelated caregiver in the home) have been associated with increased risk for abuse, these are relatively insensitive and non-specific and should not be used to confirm or exclude abuse. Serious physical abuse has been reported in every socioeconomic setting; even in households with several risk factors, the vast majority of caregivers do not physically abuse their children.

History

Abuse is challenging to recognize when a child presents with nonspecific symptoms and without a recognized traumatic injury. Occult traumatic brain injury can present with irritability, difficult arousal, seizure, or prolonged vomiting, usually without fever or diarrhea. Fractures, abdominal injuries, and mild brain injuries can have a smoldering course of mild symptoms, such as irritability or decreased appetite or activity. In these cases, identifying abuse is difficult and usually involves prolonged symptoms, additional clues on physical examination, known social risk factors, or prior concern for abuse.

Although still nonspecific, certain chief complaints should prompt consideration of abuse. A small percentage of children presenting with an apparent life-threatening event (ALTE) will have retinal hemorrhages or other abusive injuries. Occult fracture should be considered in young or pre-verbal children who present with decreased use of an extremity, fussiness, and localized tenderness or refusal to bear weight.

Regardless of the injury, an unexplained delay in seeking care should prompt concern for abuse or neglect. There is no precise time period that defines “unexplained delay in care.” Physicians should take into account the child’s symptoms and progression of disease. Even without abuse, a delay of several hours is not uncommon for children with both fractures and abdominal injuries. Conversely, even a brief delay can be concerning in a child who is limp, not breathing, actively seizing, has substantial burns, or has other obvious signs and symptoms.

Serious injury with a history of only minor trauma, or when there is no history of trauma, should raise concern for abuse. Intracranial hemorrhage is extremely uncommon from short falls (eg, from a bed or a couch) and does not result from choking on formula or saliva. Intra-abdominal and intrathoracic injuries do not commonly result from household falls, even with increased height or falls down stairs. Children with serious injuries attributed to siblings or pets should be evaluated carefully for other signs of abuse. Children who present for injuries sustained as a result of violence between their caregivers should also be evaluated for abuse.
Human bite marks are patterned bruises in circular or paired semilunar rows (Fig. 177.7) and can be caused by adults or children; a maxillary intercanine distance of more than 3 cm is more likely to be from an adult. In cases concerning for abuse, human bite marks should be swabbed to identify assailant DNA. Forensic evidence collection kits used for sexual assault (ie, rape kits) can be used to obtain, document, and store this evidence for law enforcement.

Abusive burns generally fall into three categories: immersion burns, contact burns, and cigarette burns. Immersion burns should be distinguished from pull-down scalds, which are very common in toddlers. Although pull-down scalds principally involve the upper body, immersion burns tend to involve the perineum or have a symmetric, stocking/glove distribution (Fig. 177.8). Abuse should also be considered when scalds affect a large

**Physical Examination Findings**

To identify subtle signs of abuse, infants should be completely undressed during physical examination. The fontanel, scalp, ears, oropharynx, skin, and genitalia should be specifically examined. If a growth chart is available, sudden increase in head circumference can be a sign of intracranial injury.

The most commonly identified abusive injury is bruising. Although bruises are very common in ambulatory children, any bruising in a child that is not yet able to ambulate with assistance or “cruise” is highly concerning for abuse. Less than 1% of non-cruising children have bruises noted on routine physical examination. Of children younger than 6 months old referred for an abuse evaluation with apparently isolated bruises, 50% will have an additional injury (fracture, brain injury, abdominal injury) identified.

Even in children old enough to cruise, bruises to the abdomen, neck, genitalia, or ears should raise concern (Figs. 177.1 to 177.3). The TEN-4 rule (bruising to the Torso, Ear, or Neck or bruising anywhere in children younger than 4 months old) has been shown to have 97% sensitivity and 84% specificity for abuse in a pediatric intensive care unit (PICU) population.

Certain patterned injuries raise the likelihood of abuse (eg, bruises in the shape of a cord, belt, or hand) (Figs. 177.4 to 177.6).
body surface area, sparing patterns suggest that the child was held in place, or when the incident is reported in the context of a toileting accident. 26 For scald burns, CPS or law enforcement can measure the home’s peak water temperature and the delay until peak temperature occurs. Although it takes several minutes to sustain a partial thickness burn from water at 120°F, the same burn can occur in seconds at 150°F.

As with bruises, emergency clinicians should consider abuse for young children with burns that take on the shape of an implement (eg, hair curler, grate, or lighter). Cigarettes can cause accidental or inflicted burns. Because the burning end of a cigarette can be more than 1000°F, inflicted burns are rarely superficial, and commonly result in crusted or ulcerated lesions between 8 to 10 mm. Glancing or accidental contact with a cigarette can also cause superficial, linear burns (Fig. 177.9).

Oropharyngeal injuries are also concerning in young children without a history of trauma to the mouth or throat (Fig. 177.10). 27 Tears of the lingual or labial frenula have been cited in several case series of children with missed abuse, as have unexplained injuries to the lips, teeth, or soft palate. When identified in the course of evaluation of children with other concerns of abuse, these injuries should increase concern.

Red-Flag Injuries

For many children, the concern for abuse is first raised by the unexpected or incidental identification of a traumatic injury. There are several injuries where abuse should routinely be
considered unless there is an independently verifiable history of major trauma (e.g., a motor vehicle collision).

Serious traumatic brain injury should prompt a concern for abuse in children younger than 3 years old. In one series of children admitted to the intensive care unit (ICU) with traumatic brain injuries not known to be the result of a motor vehicle collision, 43% were victims of abuse. Subdural hematomas and multifocal injury are especially concerning for abuse, whereas epidural hematomas and intraventricular hemorrhage are more likely to be non-abusive.

Similarly, intra-abdominal injuries in young children are concerning for abuse if not sustained as a result of motor vehicle collision, accidental direct blow, or significant fall. In children who sustain short falls in hospitals or other witnessed settings, intra-abdominal injuries are vanishingly rare. Although hepatic injuries are the most common abusive injury identified, small bowel perforation and pancreatic injury are especially specific for abuse.

Long-bone fractures of any type are concerning in children younger than 12 months old. Administrative data from the United States show that abuse is diagnosed in 30% to 60% of infants with fractures of the radius, ulna, tibia, fibula, femur, or humerus. Rib fractures (Fig. 177.11) were even more concerning, being associated with abuse in 69% of children younger than 12 months old and approximately 27% of children 12 to 36 months old. Less common, fractures to the hands, feet, spine, pelvis, sternum, or scapula should be considered highly concerning for abuse in young children without a specific, independent history of significant trauma.

Perhaps no fracture is more specific for abuse than the classic metaphyseal lesion (CML). Histologically, these lesions are planar fractures that extend through the primary spongiosa on the metaphyseal side of the growth plate. Radiographically, these lesions appear as chips or bucket handle lesions around the growth plate and are most commonly seen at the distal femur, proximal humerus, and proximal and distal tibia of infants with severe physical abuse (Figs. 177.12 and 177.13). The identification of a CML in an infant should prompt a thorough abuse evaluation.

Skull fractures in infants commonly raise the concern for abuse but, relative to the injuries listed earlier, are much less specific. Even in infants, linear, parietal skull fractures can result from very short falls. Because skull fractures do not show signs of healing, birth-associated skull fractures can be both clinically subtle and difficult to differentiate from acute injury. Several series have examined rates of additional fractures in infants presenting with apparently isolated skull fractures. Rates of occult fracture ranged from just over 1% to approximately 5%. Complex skull fractures—multiple fracture lines, fractures that cross suture lines, and those with substantial depression or widening—require more force or multiple impacts and are therefore more concerning. It is possible, however, for bilateral parietal fractures to result from a single impact to the cranial vertex.

Although spiral fractures were once thought to have high specificity for abuse, available data do not support this. Spiral fractures of the tibia in children learning to walk (toddler’s fractures) are among the few fractures in young children that do not require routine skeletal survey, even without a clear mechanism of trauma.

**DIFFERENTIAL DIAGNOSES**

Because the diagnosis of abuse has a profound impact on a child, his or her family, and the alleged abuser, a variety of traumatic and medical conditions have been used to explain signs and symptoms of physical abuse. These range from sincere attempts
to distinguish abuse from rare but well-described medical entities to the invention of new medical entities, which are invoked only in legal settings or the lay press when there is a concern for abuse.\textsuperscript{16,41-46} It is usually beyond the scope of an emergency clinician to test for such rare diseases or hypothetical entities unless there are specific signs or symptoms (eg, the blue sclera of osteogenesis imperfecta) or a specific family history.

The most common entity to be differentiated from abuse is accidental injury. With few exceptions (eg, the CML), most traumatic injuries that have been reported in the setting of abuse can also be seen with other severe forms of trauma.\textsuperscript{28} Isolated injuries reported in the context of an accidental trauma mechanism should be evaluated on a case-by-case basis to determine whether the identified injury matches the reported mechanism. Young children who have started to cruise or walk frequently may have unobserved short falls from standing, beds, or couches less than 3 feet high. Although the vast majority of these falls are benign, they can produce isolated bruising to shins, elbows, or other hard body surfaces; linear skull fractures; buckle fractures of the distal femur; and clavicle fractures.

In the youngest infants, injuries from birth should be considered, because symptoms may only be recognized weeks after the child is discharged from the hospital. Skull fractures, cephalhematomas, and clavicle fractures are the most commonly identified, whereas asymptomatic subdural hematomas, rib fractures, and other extremity fractures are rarer.

Bone fragility disorders should be considered in children with exclusively bony injuries.\textsuperscript{42} Osteomalacia of prematurity occurs in roughly 30\% of extremely low birth weight infants and is commonly associated with fractures in the absence of significant trauma. Risk factors include exposure to prolonged parenteral nutrition, steroids or furosemide, and those with cholestasis or chronic lung disease.\textsuperscript{47} Minor forms of osteogenesis imperfecta can present with multiple-unexplained fractures. Although the diagnosis can be made early in children with a family history or severe disease, some cases are only diagnosed in the course of an
evaluation for abuse. Be alert for blue-grey sclera, especially if they persist beyond infancy, family history of unexplained fractures, fragile teeth, congenital hearing problems, or short stature.

In children whose injuries are confined to problems of bruising or bleeding, emergency clinicians should consider an undiagnosed coagulopathy. The American Academy of Pediatrics (AAP) has published guidelines for coagulopathy testing that will identify the vast majority of bleeding disorders. Briefly, these children should have prothrombin time and international normalized ratio (PT/INR), partial thromboplastin time (PTT), Factors VIII and IX, and complete blood count (CBC). Children who present with bruising should also have testing for von Willebrand antigen and activity. Those with intracranial hemorrhage should have testing for D-dimer and fibrinogen. Because coagulopathy testing can take weeks or months, and because abuse is the more common etiology in children with isolated bruising and concern for abuse, the coagulation evaluation should not delay the evaluation for abuse, reporting to CPS, or safety planning.

DIAGNOSTIC TESTING

Protecting a child from an abusive caregiver can require proving that the child’s injuries are the result of abuse. Identification of additional traumatic injuries suggests abuse, particularly when not explained by the initial history. Although concomitant injuries may not require medical treatment, they have forensic significance. The clinical examination is insensitive, especially in very young children, for forensically significant injuries, such as healing fractures, CMLs, abdominal injuries, and even milder abusive head trauma. To decrease testing disparities and improve abuse recognition, we recommend a routine testing strategy (outlined later) based on the level of concern for abuse and the child’s presenting injuries.

Skeletal Survey

The radiographic skeletal survey is the oldest and most commonly used diagnostic test to identify occult traumatic injuries in children with concern for abuse. Depending on the population studied, skeletal surveys performed in cases of suspected abuse identify additional fractures in approximately 10% to 25% of cases. As occult fractures are more likely in young children, guidelines recommend skeletal survey for all children younger than 24 months old with abusive or suspicious injuries. In children 24 to 60 months old, the skeletal survey is still a reasonable option, especially for those with limited mobility, decreased ability to communicate, and those 24 to 36 months old. The skeletal survey is rarely useful for children older than 60 months old.

To avoid over- or under-diagnosis, proper technique for a skeletal survey requires at least 21 separate films (including oblique views of the ribs) and interpretation by an experienced radiologist. A child should be transferred to an experienced center for skeletal survey rather than have an incomplete or inadequate series. There is no role for a single exposure to a single skeletal survey. Repeated, especially if timely results are needed to determine if a child should be removed from the home.

Neuroimaging (Computed Tomography or Magnetic Resonance Imaging)

Abusive head trauma is the leading cause of death and disability in abused children. Head computed tomography (CT) scan or magnetic resonance imaging (MRI) should be undertaken in children with signs of brain injury—decreased mental status, external signs of impact to the head, bulging fontanel, seizure, coma, or focal neurological findings. However, occult head injury should also be considered. In one series, patients younger than 2 years old admitted with concern for abuse routinely underwent neuroimaging if they were younger than 6 months old or had facial bruising, rib fractures, or multiple fractures; 37% of those without other signs of head injury had an occult brain injury.

CT is the current criterion standard to diagnose abusive head trauma, because it is widely available, fast, and accurate. Head CT should routinely include three-dimensional reformattting to identify subtle skull fractures that may be missed in the plane of the scan. These reformats do not require additional radiation exposure, but they do require reformattting before data is expunged. An MRI of the brain is frequently performed several days after the initial CT scan to further delineate and assess the progression of injury. Some centers have also begun to use faster, more motion-tolerant MRI sequences (fast MRI) in place of CT as the initial test for abusive head trauma. Cranial ultrasound is not sufficiently sensitive to identify occult abusive injuries and is not recommended as an initial study for children with concern for abuse.

Retinal Examination

Retinal hemorrhages identified in a child with head injury can significantly affect the recognition of abuse. Hemorrhages that are numerous (>20), multilayered and that extend to the retinal periphery, or those associated with macular retinoschisis are strongly associated with severe traumatic brain injury and abusive head trauma (Fig. 177.14). Dedicated retinal examination by an experienced ophthalmologist is recommended for all children with concern for abusive head trauma to characterize the hemorrhages and improve sensitivity. Conversely, without radiographic evidence of brain injury, significant retinal hemorrhages are rare, and transfer or referral for specialty retinal examination should be considered optional in this group. Even in severe cases of abusive head trauma, retinal hemorrhages are absent in
Abdominal Injury Testing

Intra-abdominal injuries, ranging from obviously life-threatening to completely asymptomatic, are present in approximately 3% of children evaluated for physical abuse. Abdominal bruising, tenderness, or distention are present in approximately 50% of abusive abdominal injuries. In two large series of children younger than 60 months old evaluated for abuse, those who had either aspartate transaminase (AST) or alanine transaminase (ALT) >80 IU/L had at least 20% post-test probability of an intra-abdominal injury identified by CT scan or other definitive testing. Amylase and lipase have been recommended by some authors to increase sensitivity for abdominal injuries but have not been shown to significantly improve yield beyond clinical examination plus AST and ALT. Although ultrasound can identify abdominal injuries, it is relatively insensitive; CT should be used to characterize injuries identified by ultrasound. In children without obvious evidence of abdominal injury or history of trauma to the abdomen, we recommend routine AST and ALT testing and an abdominal CT scan with intravenous (IV) contrast for those with AST or ALT >80 IU/L. Because AST and ALT rapidly normalize, even in children with hepatic lacerations, trending of transaminases should not be used to determine the need for imaging. For this reason, it is also important that testing be completed during the initial evaluation.

Household Contacts

Violence is a disease that affects an entire household. In cases with concern for abuse, emergency clinicians should determine if other children share the child’s home, daycare, or care environment. CPS or the child’s primary pediatrician can help arrange physical examination and/or skeletal survey for contact children. In one series of children with high likelihood of abuse and at least one serious injury, household contacts younger than 24 months old had occult fractures on skeletal survey in 12% of cases; for twins the incidence were dramatically increased risk (odds ratio [OR], 20). In cases where there is significant concern for genetic diseases that mimic abuse, evaluation of biological siblings can improve diagnosis (Table 177.1).

Timing

Determining the age of an injury can affect the plausibility of an offered history and can assist law enforcement in identifying the perpetrator. In young children, multiple injuries of different ages are highly concerning for abuse. In many cases, the best way to determine the timing of an injury is based on when the child developed symptoms, or independent witness reports of when cutaneous injuries were first visible.

The best evidence for injury dating comes from fractures of endochondral bones (most bones except the skull). Signs of healing (eg, periosteal reaction and callus formation) are rarely evident before 7 days and commonly seen within 10 to 14 days.

Experienced radiologists can sometimes offer more nuanced estimates of fracture age. Conversely, emergency clinicians should be cautious not to estimate the age of bruises based on their appearance. One widely cited dating system is based on scint data and had poor accuracy when prospectively used to estimate bruise ages in children with known times of injury. Similarly, the appearance on CT of subdural hematomas or other intracranial hemorrhages is of limited utility in estimating the age of injury. Although hyperdense “bright” blood is often thought to signify acute hemorrhage (and vice-versa), hyper-acute bleeding, re-bleeding and mixing of blood and cerebrospinal fluid (CSF) probably account for their poor accuracy. Mixed density subdural hematomas have been described in several cases with a single traumatic episode and therefore are not strong evidence for multiple episodes of trauma. In cases of severe traumatic brain injury, the onset of a child’s symptoms is probably the most useful determination of timing of injury.

MANAGEMENT

Compared to children with nonabusive traumatic brain injury, as a group, children with abusive head trauma tend to have more severe injury, longer ICU stays, and higher mortality.
Non-convulsive seizures are identified in more than 30% of children with abusive head trauma, prompting some to recommend routine electroencephalogram (EEG) monitoring. Otherwise, medical management of children with abusive traumatic injuries is generally the same as for non-abused children. Beyond the management of the acute injuries themselves, management of abuse largely consists of secondary prevention—protecting the child from further abuse.

**Mandated Reporting**

In the United States, Canada, and several other jurisdictions, emergency clinicians are mandated to report a reasonable concern of child maltreatment to public CPS agencies or law enforcement. These reports can mobilize social resources for family, expand the investigation of abuse beyond the hospital, and facilitate testing or protection for other children in the abusive environment. A final diagnosis of abuse is not required to trigger the mandate, and reporters generally have legal protection for reports made in good faith, even if a child is ultimately determined not to have been abused. In cases where there is reasonable concern for abuse but where the final diagnosis is pending, clinicians should be assured that a mandated report need not automatically trigger the removal of a child from their home or the instigation of criminal proceedings. In many jurisdictions, the mandate to report can be satisfied by reporting to a designated child protection team who will complete the evaluation and determine the need for reporting.

Hospital social workers can assist with the reporting process. The exact procedure for reporting varies by jurisdiction, but instructions are usually accessible by any Internet search engine searching for “report child abuse [location].” In preparing to report, gather the child and family’s contact information, the identity of any other children in the home, and the location where the abuse occurred to determine which agency has jurisdiction.

**DISPOSITION**

Many children with physical abuse will require hospital admission for treatment and stabilization of their injuries or identification of a safe environment. Children with concern for physical abuse may be discharged if (1) injuries have been medically stabilized, (2) reasonable concerns for abuse have been reported as required by statute, and (3) a safe environment has been identified. In children who are otherwise stable for discharge, CPS can work with families to establish a temporary safety plan in which the child is placed in the care of a friend or family member.

**SEXUAL ABUSE**

**PRINCIPLES**

Sexual abuse of children is common and under-recognized. Among 17-year-olds, a history of sexual abuse was self-reported in 26% of girls and 5% of boys with the highest rates occurring in adolescence. These are likely under-estimates given the limitations of self-reporting. Perpetrators of sexual abuse are overwhelmingly male and can include family members, acquaintances, or strangers.

As with physical abuse, the bulk of the investigation in cases with concern for sexual abuse can occur outside of the ED. Urgent interventions include stabilization of medical injuries, evidence collection or post-exposure prophylaxis (PEP), arrangement of a safe environment, and reporting. Evaluation of children more than 72 hours after possible abuse (or another period if mandated by law) can be deferred from the ED to an outpatient setting.

Completion of a full evidence collection kit can require more than an hour of undivided attention, and emergency clinicians responsible for multiple potentially unstable patients may benefit in partnering with a sexual assault nurse examiner (SANE) program or subspecialty child abuse pediatrician.

Misconceptions about normal pediatric female genital anatomy (Fig. 177.15) are widespread among both patients and emergency clinicians. Normal configurations for the pediatric hymen include annular or ring-shaped, crescent-shaped and tulip-shaped, among others. Although imperforate hymens exist and can cause symptoms in pubertal children, this is a rare abnormality.

**CLINICAL FEATURES**

In contrast to physical abuse, most sexual abuse evaluations will be prompted by a patient or caregiver report. Genital bleeding or discharge should prompt consideration of sexual abuse in pre-verbal children or those who do not report sexual abuse. Pregnancy or sexually transmitted infections (STIs; gonorrhea, chlamydia, syphilis, trichomonas, or human immunodeficiency virus [HIV]) provide evidence of sexual contact.

Identification of pregnancy in a young adolescent should prompt nonjudgmental questions about the girl’s sexual partners; some victims perceive abuse as consensual sexual activity with a “boyfriend.”

Caregivers sometimes bring children for evaluation based on concern for abnormal appearance of a child’s genitalia (redness, size, or shape of vaginal or rectal orifices). Without other indications of abuse, these findings are extremely nonspecific and do not increase the likelihood of abuse. In young children (2 to 6

**KEY CONCEPTS**

- The emergency department (ED) evaluation should focus on identifying and treating medical injuries, recognizing patterns suspicious for abuse, and establishing a safe disposition for the child. The ultimate determination of whether abuse has occurred can require days or weeks.
- Maintain an objective, matter-of-fact manner when evaluating children for abuse.
- Social factors are not sensitive or specific for abuse and may be hidden from the emergency clinician. Consider abuse routinely for serious injuries in young children without an independently-witnessed traumatic mechanism.
- Completely undress infants and pre-verbal children for the physical examination; pay particular attention to the skin, ears, mouth and oral cavity, scalp and fontanel, and genitalia.
- Without an independently witnessed severe trauma, injuries that should routinely prompt an evaluation for abuse include bruising in infants younger than 6 months old; bruising on the torso, ears, or neck; unexplained oral injuries; patterned cutaneous injuries; subdural hematoma; long-bone fractures in infants; intra-abdominal injuries; and rib fractures.
- Diagnostic testing should identify both clinically and forensically significant injuries and for physical abuse should include a skeletal survey in children younger than 2 years old.
- Emergency clinicians in the United States and Canada are legally mandated to report reasonable concerns for abuse.
Consider asking “where,” “what,” or “who” questions to understand the timeline. For example, a child who does not know what time or day something occurred may know whether it was day or night, it was a school day or a weekend, or whether it occurred during a specific holiday or event. It may be helpful to elicit the terms used by the child to describe different body parts.

Because forensic interviewing requires substantial training and ongoing peer review, and due to concern that repeated interviews could “contaminate” evidence, parents and caregivers should be counseled not to question the child before the formal forensic interview. However, they should also provide a safe, supportive, listening environment if the child approaches them with information or questions. Outcomes for sexually abused children are improved when they are believed and supported by their caregivers.

Most children who present to the ED with concern for sexual abuse should undergo dedicated physical examination of the genitalia and rectum. With proper preparation, this examination need not be painful or distressing to the child. Conducting the examination on the lap of a trusted caregiver and in the context of other painless examination maneuvers (inspecting the nose, heart, and belly-button) can reassure the child. Informing the child that this examination “is okay because I am a doctor, because Mom is here, and because Mom says it’s okay” helps distinguish the examination from inappropriate sexual contact.

During puberty, the hymen develops from a thin, smooth rim of tissue to a thicker, redundant mucosal ridge. The pre-pubertal (non-estrogenized) hymen is exquisitely sensitive; touching it will almost certainly end the useful portion of your examination. For this reason, a speculum examination should not be conducted in a pre-pubertal child. To avoid additional trauma, a genital examination should never be forced on a reluctant child. In most cases, a child can return for an outpatient examination after food, rest, and preparation. In the rare cases of substantial bleeding or concern for a medically unstable injury, a gynecologist should perform an examination under anesthesia.

To best expose the hymen and other relevant anatomy, pull the labia majora out (off the table or toward the examiner—not laterally) with the same force you would use to retract the cheek to examine the teeth. The posterior hymen, if not sufficiently visualized in this position, can sometimes be better seen in the “knee-chest” position, where the child is placed in a prone position on the examination table with their hips flexed so that their knees and chest are resting on the table. The posterior hymen is then visualized by laterally retracting the buttocks.

If manipulation of the hymen is absolutely necessary, consider using the mucosal surface of the contralateral labia to manipulate the hymen. Alternatively, a few drops of sterile saline can be used to “float” the posterior rim of the hymen and expose an area of interest. A colposcope can be useful to magnify, illuminate, and document examination findings. Data do not support the use of toluidine blue to identify mucosal injuries not apparent to the naked eye.

Although the vast majority of physical examinations will be normal, even when performed soon after acute sexual assault, a normal examination does not exclude abuse. Children and families can be reassured that they are healthy and normal and that no one in the future (eg, doctors, spouses) will know from looking at them that abuse has occurred. Some families have concern for an anatomic definition of virginity, although they are reluctant to broach the issue. Providers should emphasize that the child is anatomically normal and that the definition of virginity should depend on when someone chooses to have intercourse.

A wide array of nonspecific findings (eg, erythema, periurethral bands, and bumps and notches of the hymen) should not be confused with evidence of sexual contact. Injuries that are indicative of trauma include bruising, petechiae, or abrasions on the...
hymen; acute lacerations of the hymen; vaginal lacerations; or complete transection of the hymen between 4 o’clock and 8 o’clock (Figs. 177.16 and 177.17). In adolescents capable of consensual sexual activity, no examination finding can distinguish consensual sexual activity from assault or rape (Table 177.2).

**DIFFERENTIAL DIAGNOSES**

Strep infection of the perineal skin and genitalia can produce redness, inflammation, and fissures. Vaginitis from infection or poor hygiene can result in vaginal discharge or dysuria. Isolated vaginal bleeding can be the result of urethral prolapse (beefy red protrusion inferior to clitoral hood) or lichen sclerosis (pale, irritated, thin, hypopigmented skin surrounding the genitalia; Figs. 177.18 and 177.19). Straddle injuries can produce bruising of the external genitalia (labia, perineum, and peri-urethral tissues) and are usually accompanied by a history of injury. In boys who are toilet training, a falling toilet seat can produce dorsal and ventral penile bruising similar to a bite mark. Many laxatives are skin irritants, and diapered children who are treated for constipation may develop erythema or blistering if stool remains in contact with the skin.

**DIAGNOSTIC TESTING**

The goal of diagnostic testing in the ED is to identify transient evidence of sexual assault or sexually transmitted diseases. Beyond the history and physical examination, a forensic evidence collection kit (“rape kit”) can provide evidence of sexual contact and identify the assailant if DNA is isolated. Evidence is more likely to be obtained soon after the assault with the majority of positive kits obtained within 24 hours.\(^7\)\(^9\)\(^{10}\) Forensic evidence collection is recommended for cases of assault with possibility of DNA transmission (semen, blood, or saliva) up to 72 hours from the assault, although some practitioners or jurisdictions are moving to a threshold of up to 7 days based on newer polymerase chain reaction (PCR)-based techniques. Beyond 24 hours, specimens from the child’s clothing are the most likely to retain evidence. Obtaining the child’s underwear (even if not worn at the time of the assault) can recover DNA evidence beyond 24 hours and is relatively noninvasive. Although many kits require documentation of whether a child has eaten, defecated, urinated, or wiped prior to evidence collection, these should not impact the decision to collect evidence.

Pregnancy testing is routinely obtained in pubertal females because levonorgestrel (Plan B) is ineffective for established pregnancies. STI testing is undertaken for symptomatic patients or in cases with potential for subacute or chronic abuse. Determining which tests to obtain depends on the details of the child’s...

---

Potential exposure and their physical examination, as well as local disease prevalence, patient and parent preferences, and the availability of timely follow-up. Emergency clinicians may benefit from case-by-case consultation with child abuse pediatrics or infectious disease colleagues.

Although STI transmission in pediatric assault is uncommon (5% to 8%), the advent of nucleic acid amplification testing (NAAT) in place of a culture has expanded the use of testing for gonorrhea, chlamydia, and trichomonas; NAAT has improved sensitivity, lower cost, and can be collected more easily. NAAT testing has been endorsed by the Centers for Disease Control and Prevention (CDC) for urine or vaginal specimens in girls. Based on CDC recommendations from 2010, we recommend testing children for sexual abuse when there are symptoms of STI, there is a known STI or risk factors for STI in the alleged perpetrator, an STI has been identified in a contact of the patient, physical examination findings show evidence of sexual contact or ejaculation, and when requested by the patient or the parent when there is reasonable concern for sexual abuse.

Currently, there are no guidelines to direct testing for syphilis, hepatitis B or C, or HIV in children following sexual assault. We recommend testing in children with absent or incomplete hepatitis B vaccination, symptoms or diagnosis of another STI, known STI or risk factors in the alleged assailant, STI in a sibling or contact, or with patient or parent request when there is reasonable concern for abuse. Initial screening for syphilis should be by rapid plasma regain (RPR); hepatitis B screening should include hepatitis B surface antigen and hepatitis B virus (HBV) immunoglobulin M (IgM) core antibody. Testing for HIV and hepatitis B and C should be repeated 6, 12, and 24 weeks after sexual contact.
MANAGEMENT

ED management should focus on the most time-dependent interventions, mandated reporting, and PEP for pregnancy and HIV. When there is a reasonable concern for sexual abuse, reporting to CPS is mandatory for physicians in the United States, Canada, and many other countries. Some caregivers may strongly desire reporting to children’s services, even when the findings do not meet the threshold of a reasonable concern for abuse (as when the child presents for isolated nonspecific redness of the genitalia without a disclosure of abuse). Should the emergency clinician opt not to report these cases, caregivers can be advised that they have the option to report their concerns to CPS directly, independent of the health care provider.

Levonorgestrel (Plan B) should be offered to pubertal females within 120 hours (5 days) of sexual assault. When taken within 72 hours, it can prevent up to 50% of pregnancies, although there is some potential to prevent pregnancy up to 120 hours after sexual assault. Because it works by suppressing ovulation, patients can be reassured that it will not terminate an established pregnancy.

The decision to offer PEP for HIV is complex and depends on the nature, timing, and likelihood of the sexual assault; local prevalence of HIV; and likelihood that the perpetrator is HIV positive. Although rates of HIV transmission in the course of sexual assault are probably low, cases of HIV in children whose only risk factor is abuse have been reported. The CDC maintains a national telephone consultation service (1-800-933-3413) to provide real-time expert consultation to emergency clinicians with questions about HIV PEP.

Prophylaxis or empirical treatment for gonorrhea, chlamydia, or trichomonas may be offered to pubertal children but should be deferred for pre-pubertal children. In pre-pubertal children, consensual sexual activity is impossible by definition, rates of STD are low, ascending infection is very uncommon, and follow-up is usually obtainable. For these reasons, the medical consequences of delayed treatment are low, but the forensic significance can be profound. Because infection with gonorrhea, chlamydia, or trichomonas is usually strong evidence of sexual abuse in pre-pubertal children, proof of infection can be essential to ensure the child’s protection from ongoing abuse. Treatment prior to obtaining proof of infection can limit confirmatory testing and thwart protection efforts (Table 177.3).

DISPOSITION

The vast majority of children evaluated for sexual abuse in the ED can be discharged to follow-up as outpatients. Medically stable patients can be discharged to a safe environment after obtaining appropriate testing and evidence collection. When the alleged assailant is a member of the child’s household, CPS can arrange safety planning to ensure that a child has a safe place for discharge or that the alleged assailant is removed from the child’s home.

CHAPTER 177: QUESTIONS & ANSWERS

177.1. A 12 month-old girl is referred to the emergency department (ED) because her daycare noticed that she cried whenever she is picked up and crepitus in the left side of the chest. They deny any witnessed trauma in the daycare facility. The mother arrives and appears concerned. On physical examination, you find some circular contusions on the inner aspect of the upper arm. The mother states this occurred from a fall a week ago. Which of the following should be the next step in the patient’s management?
A. Conduct a skeletal survey, and call child protective services (CPS) as a mandated reporter.
B. Discharge the patient if a thorough physical examination is normal.
C. Determine whether the arm contusions are of the same age.
D. Perform a dedicated retinal examination to determine if the child has retinal hemorrhages and, if she performs, a head computed tomography (CT) scan.
E. Perform a humerus x-ray to determine if there is a humerus fracture.

Answer: A. Contusions on the inner aspect of the upper arm are atypical injuries in light of the mother’s claim of a fall for the child. This pattern of injury is often related to being held tightly around the arm. Chest wall pain in a child could indicate a rib fracture. Chest x-ray is insensitive for rib fractures, which are very uncommon at this age unless caused by inflicted trauma. This should raise your suspicion of child physical abuse. In general, children younger than 2 or 3 years old with suspected inflicted injuries should be evaluated with a skeletal survey.

177.2. In a 12 month-old, which of the following fractures are very concerning for abuse?
A. Metaphyseal fracture of the radius
B. Occipital skull fracture
C. Spiral fracture of the tibia (toddler’s fracture)
D. Both A and B
E. All of the above

Answer: D. A toddler’s fracture, also referred to as a CAST (childhood accidental spiral ribial) fracture, occurs when there is a twisting injury to the tibia as the child falls on it. In toddlers, this is usually an accidental injury. In particular, metaphyseal fractures, rib fractures, scapula fractures, and certain types of skull fractures should raise concern about inflicted trauma.

177.3. An 8-year-old girl presents after sexual assault in which she reports penile-vaginal penetration 8 hours prior to presentation. Which of the following is not indicated?
A. Consideration of human immunodeficiency virus (HIV) post-exposure prophylaxis (PEP) based on local disease prevalence, other risk factors, and patient preferences
B. Genital examination
C. Prophylactic/empirical treatment for gonorrhea and chlamydia
D. Report to child protective services (CPS) and/or law enforcement
E. Testing for gonorrhea and chlamydia

Answer: C. Prophylactic/empirical treatment for gonorrhea and chlamydia is not recommended in the emergency department (ED) for pre-pubertal children because the forensic significance of these diseases far outweighs their clinical significance. Gonorrhea and chlamydia very rarely ascend to the upper genital tract in pre-pubertal children, and the risk of long-term complications of deferred treatment is therefore low.

177.4. Which of the following is not a finding suggestive of an underlying medical condition?
A. Blue sclera, brown discolored teeth, and frequent fractures
B. Bruises on both buttocks and flanks after jumping off the bed
C. Dark discoloration in the shape of a hand after making lemonade in the sun
D. Dark discoloration over lower spine present since first week of life
E. Osteopenia in a premature infant

Answer: B. Non-inflicted bruises are usually unilateral, occurring on the side where a fall or collision with a solid object has occurred. Bruises on the buttocks and flank must be explained by the mechanism of injury and are unusual in non-inflicted trauma. Phytophotodermatitis may be mistaken for bruises. This is a condition that develops on sun-exposed areas of the body that have been in contact with certain fruits or juices, such as lime or lemon juice. Premature infants may experience osteopenia of prematurity. Osteogenesis imperfecta, a brittle bone disease, is associated with other clinical findings, such as blue sclerae and brown discoloration of the teeth (dentinogenesis imperfecta). Dermal melanocytosis (Mongolian spots) are bluish discolorations that are seen normally over the buttocks and lower spine in children with darker complexions.

177.5. An otherwise healthy 3-month-old boy is brought to the emergency department (ED) in a deep coma.
Caregivers report that he was completely normal until 30 minutes prior to arrival when he suddenly seized. He is obviously ill with a pediatric Glasgow Coma Score (GCS) of 3. A head computed tomography (CT) scan shows bilateral subdural hematomas. Which other testing is not indicated to determine the likelihood of abusive injury?

A. Aspartate transaminase (AST)/alanine transaminase (ALT) with abdominal CT if these are abnormal
B. Dedicated retinal examination by an ophthalmologist
C. Determine whether there are other children in the home
D. Skeletal survey when the child is clinically stable
E. Testing for osteogenesis imperfecta

**Answer: E.** Osteogenesis imperfecta is an important consideration in children when the concern for abuse is based exclusively on bony injuries (fractures). It does not cause traumatic brain injury. All Children with concern for abusive head trauma should have a dedicated retinal examination to determine whether there are retinal hemorrhages or other retinal findings of abuse. Testing for abdominal injuries or fractures can identify additional abusive injuries. Young children (<24 months old) who share a home with an abused child are at high risk for abuse, especially twins.

177.6. In a 2-week-old infant that is not yet crawling, which of the following is most highly concerning for abuse?

A. Clavicle fracture with callous
B. Lateral rib fracture with obvious callous
C. Parietal skull fracture without callous
D. Torn lingual frenulum with scant bleeding
E. All of the above

**Answer: D.** Lingual frenulum tears are very concerning for abuse in pre-mobile infants. These injuries heal quickly, and the presence of bleeding excludes the possibility of birth injury. Several self-limited injuries can result from the birth process, even in deliveries that are not recognized as particularly traumatic. These injuries can be clinically subtle and are not-uncommonly missed in the newborn nursery. Rib fractures are uncommonly seen from birth and are more common in larger infants or difficult deliveries. The presence of obvious callous on the rib fractures is consistent with a fracture that is at least 7 to 14 days old. Clavicle and skull fractures are not uncommon parturitional injuries. Unlike other fractures, skull fractures do not develop callous and their age cannot be estimated.

177.7. Which of the following can be used to estimate the age of an injury?

A. Color can be used to estimate the age of a bruise within 12 to 24 hours.
B. Density on computed tomography (CT) scan can be used to estimate the age of subdural hematomas within 1 to 2 days.
C. Intensity on magnetic resonance imaging (MRI) can be used to estimate the age of subdural hematomas within 1 to 2 days.
D. The presence of periosteal reaction can be used to estimate the age of a fracture within 1 to 2 weeks.

**Answer: D.** Several studies have demonstrated that periosteal reaction and callous begin to become visible after 1 to 2 weeks. Conversely, neither color of bruising nor appearance of subdural hematomas on CT scan or MRI has been shown to reliably correlate with timing. The age of retinal hemorrhages cannot be precisely determined by their appearance.

177.8. Which injury is most concerning in light of the reported mechanism?

A. A 6-month-old with a linear, parietal skull fracture after a 3-foot fall from a bed to a hardwood floor
B. A 13-month-old, unrestrained passenger in a high-speed motor vehicle collision who has a large subdural hematoma and a few retinal hemorrhages around the optic nerve
C. A 27-month-old who with a small bowel perforation and pancreatic laceration after a fall down eight steps
D. An 18-month-old who presents with a spiral tibia fracture and no history of trauma
E. A 10-year-old who presents with a spiral femur fracture after a crash while skiing

**Answer: C.** Intra-abdominal injuries of any kind are uncommon after short falls or stairway falls. Hollow-viscus ruptures and pancreatic injuries are particularly concerning for abuse. Although spiral fractures have been thought to be particularly concerning for abuse, more recent data has not supported this. Spiral tibia fractures (toddler’s fractures) are common among children learning to walk, and spiral femur fractures are plausible from injuries if there is sufficient energy and a torqueing mechanism. Too numerous to count retinal hemorrhages in multiple layers and throughout the retina are relatively specific for abusive head trauma, but severe non-inflicted head injuries can also result in retinal hemorrhages that are few, and localized to the posterior retina. Linear, parietal skull fractures can result from relatively minor trauma.

177.9. A 13-month-old girl with an abusive femur fracture and a small abdominal bruise is found to have AST 475 and ALT 300. The next most appropriate step to identify an abusive abdominal injury is:

A. Abdominal computed tomography (CT) scan with intravenous (IV) contrast
B. Amylase, lipase, urinalysis, and white blood cell count
C. Focused abdominal sonography in trauma (FAST) ultrasound
D. Formal abdominal ultrasound
E. Repeat aspartate transaminase (AST)/alanine transaminase (ALT) in 6 to 12 hours to determine whether values are worsening

**Answer: A.** Abusive abdominal injuries can be clinically subtle, and even small injuries that are clinically self-limited can have important forensic significance. Children with severe abusive injuries should have hepatic transaminase testing to identify occult abdominal injuries and those with clinical signs of abdominal injury or with elevated transaminases (>80 IU/L) should undergo abdominal CT scan with IV contrast. Other laboratory tests and ultrasound are relatively insensitive for traumatic intra-abdominal injuries. Whether or not there is an injury, elevated hepatic transaminases almost always normalize quickly over time.

177.10. A 10-year-old, pre-pubertal girl presents to the emergency department (ED) at midnight after reporting to her parents that she was sexually abused 2 weeks ago while at summer camp. The patient is tired and irritable at the time of presentation. Which of the following are indicated in the ED?

A. Human immunodeficiency virus (HIV) post-exposure prophylaxis (PEP)
B. Obtain a detailed history of the assault including the time, place and circumstances of all sexual contact
C. Pregnancy prophylaxis with levonorgestrel (Plan B)
D. Report to child protective services (CPS)
E. Urgent genital examination

Answer: D. For sexual abuse that has occurred more than 1 week prior to presentation, ED management should include fulfilling the mandate to report to CPS and ensuring that the child has a safe place for discharge. A genital examination may be attempted in a cooperative patient and can assist in assuring the child that they are normal and healthy, but the examination should not be forced on the child if they are reluctant; and it is unlikely to identify transient evidence of sexual contact at this time. The detailed forensic interview should be conducted by a trained interviewer and may be deferred until the patient is rested. Plan B and HIV PEP are unlikely to be effective 2 weeks after the assault, and pregnancy prophylaxis is not indicated for pre-pubertal children.
Acute complications of pregnancy can appear in all trimesters and pose challenges in diagnosis and management for the emergency clinician. Life-threatening disorders, such as ectopic pregnancy in early pregnancy, pregnancy-induced hypertension in mid to late pregnancy, and abruptio placentae in late pregnancy, are relatively common. Emergency clinicians must consider the signs and symptoms, stage of pregnancy, and hemodynamic stability of the patient in developing diagnostic and treatment strategies.

PROBLEMS IN EARLY PREGNANCY

Miscarriage

Miscarriage, the most common serious complication of pregnancy, is defined as the spontaneous termination of pregnancy before 20 weeks of gestation. Fetal demise after 20 weeks of gestation or when the fetus is more than 500 g is considered premature birth. Loss of early pregnancy, defined as the detection of human chorionic gonadotropin (hCG) within 6 weeks of the last normal menstrual period, occurs in approximately 20% to 30% of pregnancies. Embryonic and fetal loss after implantation occur in up to one-third of detectable pregnancies. The risk of miscarriage rises with increasing maternal age (a fivefold increase in those >40 years compared with those 25–29 years), increasing paternal age, alcohol use, increased parity, history of prior miscarriage, poorly controlled diabetes mellitus and thyroid disease, obesity, low prepregnancy body mass index, maternal stress, and history of vaginal bleeding. Approximately 80% of miscarriages occur during the first trimester; the rest occur before 20 weeks of gestation.

Approximately 25% of clinically pregnant patients experience some bleeding. It is estimated that up to 50% of all women who have bleeding during early pregnancy miscarry, although the risk is probably higher in the emergency department (ED) population. Patients who have a viable fetus visualized on ultrasound examination have a much lower risk of miscarriage (3%–6%), although vaginal bleeding is a high-risk indicator, even when a viable fetus is present. Those with a history of bleeding who do not miscarry may have otherwise normal pregnancies, although they have an approximately twofold increased risk of premature birth and low-birth-weight infants.

Pathophysiology

Most miscarriages are due to uterine malformations or chromosomal abnormalities, which account for the majority that occur within 10 weeks of gestation. In some cases, the ovum never develops (anembryonic gestation). In most early miscarriages, fetal death precedes clinical miscarriage, often by several weeks. Although clinical symptoms of miscarriages are most common between 8 and 12 weeks of gestation, sonographic evidence in most cases demonstrates death before 8 weeks; if fetal viability can be demonstrated by cardiac activity and a normal sonogram, the subsequent risk of fetal loss decreases significantly.

Maternal factors that increase the risk of miscarriage include congenital anatomic defects, uterine scarring, leiomyomas, and cervical incompetence. Other conditions associated with increased miscarriage rates include toxins (eg, alcohol, tobacco, and cocaine), autoimmune factors, endocrine disorders including luteal phase defects, a prior history of miscarriage, and occasional maternal infections.

Terminology

Miscarriage can be broadly divided into three categories. The first is a threatened miscarriage, in which the patient presents with vaginal bleeding but is found to have a closed internal cervical os. The risk of miscarriage in this population is estimated at 35% to 50%, depending on the patient’s risk factors and severity of symptoms. If the internal cervical os is open, the miscarriage is considered inevitable. If products of conception are present at the cervical os or in the vaginal canal, the miscarriage is termed incomplete, the second classification of miscarriage. The third classification is a termed a completed miscarriage, which occurs when the uterus has expelled all fetal and placental material, the cervix is closed, and the uterus is contracted. Establishing the diagnosis of completed miscarriage in the ED is difficult. A gestational sac should be visualized for diagnosis because the cervix may close after an episode of heavy bleeding and clot passage without or after only partial expulsion of the products of conception. Unless an intact gestation is passed and recognized, a completed miscarriage should be diagnosed only after dilation and curettage (D&C), with pathologic confirmation of gestational products, demonstration by sonography of an empty uterus with a prior known intrauterine pregnancy (IUP), or reversion to a negative pregnancy test result. This may take up to several weeks after the initial presentation.

Missed abortion is a relatively obsolete term referring to the clinical failure of uterine growth over time. The terms anembryonic gestation (when no fetus is visualized on ultrasound), first-or second-trimester fetal death (failure to see fetal cardiac activity with at least a 5-mm crown-rump length), and delayed miscarriage are more appropriate.

Clinical Features

Patient history should include the estimated length of the gestation, time since the last menstrual period, symptoms of pregnancy,
including evolution or loss of pregnancy symptoms, degree and duration of bleeding, presence of cramps, pain, or fever, and attempts by the patient to induce miscarriage. Although the history is important, it is not helpful in the classification of the type of miscarriage. In addition, the severity of symptoms does not correlate well with the risk of miscarriage, although cramping and passage of clots are thought more likely to occur as the miscarriage becomes inevitable.

The assessment of the patient who experiences first-trimester vaginal bleeding includes a careful abdominal examination to evaluate for tenderness or peritoneal irritation from a potential ectopic pregnancy and to determine the size of the uterus, which should not be palpable abdominally. A pelvic examination should be performed to evaluate whether the cervix is closed or open, look for clots or the products of conception, and determine the degree of vaginal bleeding, as well as uterine size and tenderness. The cervix should be gently probed with a ring forceps (not a cotton-tipped applicator) to determine whether the internal os (1.5 cm deep to the external os) is open or closed. This is unnecessary in the patient who has a clearly open os or visible products of conception but can be safely performed during the first trimester as long as the forceps are used gently and do not penetrate the cervix more than 2 or 3 cm. In the patient with second-trimester bleeding, probing should not be done because the uterus is more vascular, and the organized placenta may overlie the cervical os. Parous women normally have an open or lax external os, a finding of no significance. The adnexa may be enlarged, often unilaterally, because the corpus luteum is cystic or because the pregnancy is ectopic. Significant adnexal or uterine tenderness should always raise the possibility of an ectopic pregnancy. Much less commonly, pelvic infection can cause uterine and adnexal tenderness during early pregnancy.

Diagnostic Testing
A hemoglobin level is useful to provide a baseline measurement and evaluate the degree of blood loss in women whose bleeding persists. In addition, the Rh type should be determined. Ultrasoundography is the primary means of evaluating the health of the fetus as well as its location (Table 178.1). Because historical and clinical estimations of gestational age are often inaccurate, ultrasoundography is useful to provide an accurate measure of fetal age and viability (Box 178.1).

In the stable patient with threatened miscarriage, expectant management may be sufficient to determine when intervention is needed, as long as ectopic pregnancy has been excluded. Serial quantitative hCG levels are used to assess the health of the fetus if sonographic findings are indeterminate or if the gestational age is less than 6 to 7 weeks. The sonographic discriminatory zone is defined as the quantitative hCG level at which a normally developing IUP should reliably be seen. Discriminatory levels are operator- and equipment-dependent and vary by individual patient characteristics, but are usually considered to be 6500 mIU/mL for transabdominal ultrasonography and 1000 to 2000 mIU/mL for transvaginal ultrasonography. Ultrasonography can be performed or repeated when hCG levels rise to 1500 to 3000 mIU/mL. If hCG levels are flat or decline, or if sonographic criteria for fetal demise are demonstrated (see Box 178.1), the patient should be referred to an obstetrician for follow-up to ensure miscarriage completion and to rule out subsequent complications.

Differential Diagnosis
Ectopic pregnancy can masquerade as a threatened miscarriage in the early stages of pregnancy and should always be considered in the differential diagnosis. Even in the patient with painless vaginal bleeding, the diagnosis of ectopic pregnancy must be considered. Early ultrasonography is imperative to locate the pregnancy in the patient who has bleeding or pain.

Other diagnoses should also be considered. A small amount of bleeding occurs at the time of implantation of the blastocyst into the endometrium and, occasionally, at the time of the first missed menses. Molar pregnancy is also characterized by vaginal bleeding, usually during the late first trimester or second trimester. This condition can be identified by ultrasonography. Cervical and vaginal lesions can also cause local bleeding and can usually be seen on vaginal inspection.

Management
After assessment of hemodynamic status and management of blood loss, a patient with a threatened miscarriage requires very little specific medical treatment. Anti-D immune globulin should be administered if the patient is Rh-negative. A 50-µg dose is used during the first trimester and a full 300-µg dose after the first trimester. Once ectopic pregnancy has been excluded, ultrasonography can be scheduled more routinely at a later time for the patient without significant pain. However, the patient should be made aware that the potential for ectopic pregnancy exists until it is excluded by identification of an IUP. In the patient who is planning pregnancy termination, prompt referral should be encouraged and chorionic villi confirmed at the time of uterine evacuation.

Unless an IUP is diagnosed, the patient with threatened miscarriage should be given careful instructions on discharge to return if she has signs of hemodynamic instability, significant

pain, or other symptoms that might indicate ectopic pregnancy (so-called ectopic precautions). In conjunction with gynecologic colleagues, an ED protocol is useful to determine when follow-up sonographic evaluation and serial hCG measurements should be obtained, because ultrasonography can be an inaccurate diagnostic tool if the hCG level is below 1500 mIU/mL, vaginal bleeding is significant, or sonographic findings do not include a fetal pole or yolk sac.15,16

Although 50% or more of women with threatened miscarriage who are seen in the ED ultimately miscarry, treatment to prevent miscarriage is not useful because most fetuses can be shown to be nonviable 1 to 2 weeks before symptoms occur. In most cases, spontaneous miscarriage is the body’s natural method of expelling an abnormal or undeveloped (blighted) pregnancy. Thus, a major goal of early management should be patient education and support. Patients should be advised that moderate daily activities do not affect the pregnancy. Tampons, intercourse, and other activities that might induce uterine infection should be avoided as long as the patient is bleeding, and she should return immediately for fever, abdominal pain, or a significant increase in bleeding. Cramping from a known IUP can be safely treated with oral synthetic narcotics, if needed. If the patient passes tissue, it should be brought to a provider to be examined for products of conception because differentiation of fetal parts or villi from decidual slough or casts is difficult.

Patient counseling is paramount with threatened miscarriage.15,16 Determination of fetal viability can be helpful in reassuring the mother or preparing her for probable fetal loss.14 Miscarriages are associated with a significant grieving process, which is frequently more difficult because early pregnancy is unannounced, and early fetal death is not publicly recognized. Because many women consider that minor falls, injuries, or stress during the first trimester can precipitate miscarriage, patients should be reassured that they have done nothing to cause miscarriage. It is important to make them aware that miscarriage is common, grieving is normal, and counseling may be beneficial.

A follow-up appointment should be scheduled after miscarriage to support the patient in resolving such issues. Treatment of the patient with incomplete miscarriage includes expectant management, medical management with misoprostol, or surgical evacuation.15 When the miscarriage is incomplete, the uterus may be unable to contract adequately to limit bleeding from the implantation site. Bleeding may be brisk, and gentle removal of fetal tissue from the cervical os with ring forceps during the pelvic examination often slows bleeding considerably. Management of patients with presumed completed miscarriage is more complicated. If the patient brings tissue with her, this should be sent to the pathology department for evaluation. Unless an intact gestational sac or fetus is visualized, it is rarely clear clinically whether miscarriage is complete. Studies have shown that in women with a history consistent with miscarriage who have shown minimal remaining intrauterine tissue as determined by ultrasonography, expectant management is safe, but only if ectopic pregnancy can be excluded.17 If endometrial tissue is not seen with ultrasonography, bleeding is mild, and gestational age is less than 8 weeks, curettage is frequently unnecessary, and the patient can be safely observed by a gynecologist for serial hormonal assays. Up to 80% of women with first-trimester miscarriage complete the miscarriage without intervention.15 However, the need for later visits and procedures may be decreased by uterine curettage, particularly if the fetal pole or a gestational sac is visible on the sonogram at the time of evaluation. Medical management with misoprostol instead of D&C is also an option and has a success rate of up to 96%.15 The patient should be instructed to return if uncontrolled bleeding, severe pain or cramping, fever, or tissue passage occurs. Follow-up is recommended in 1 or 2 weeks to ensure that the miscarriage is complete.

After miscarriage, the patient should be advised that fetal loss, even during the first trimester, can cause significant psychological stress. Follow-up in 1 or 2 weeks with a gynecologist should be provided. Some physicians prescribe antibiotics after D&C or miscarriage (usually doxycycline or metronidazole), although there is no conclusive evidence to support this practice, and some evidence has suggested that the side effects of treatment may outweigh any potential benefit.15,16 Ergonovine or methylergonovine (0.2 mg orally bid) can be used to stimulate uterine involution. The patient should be advised to return if signs of infection (eg, fever, uterine tenderness) occur, bleeding resumes, or further tissue is passed.

Ectopic Pregnancy

Principles

Ectopic pregnancy, or pregnancy implanted outside the uterus, is an increasingly frequent problem that poses a major health risk to women during the childbearing years. It is the third leading cause of maternal death, responsible for 4% to 10% of maternal mortality.20 Ectopic pregnancy is estimated to account for approximately 2% of all pregnancies, although national estimates of incidence are difficult to determine.22 Although the incidence of ectopic pregnancy is highest in women aged 25 to 34 years, the rate is highest among older women and women belonging to minority groups. Simultaneous intrauterine and extrauterine gestations (heterotropic pregnancy) have historically been rare, occurring in approximately 1 in 4000 pregnancies; more recently, women who have undergone assisted reproduction techniques with embryo transfer have a demonstrated risk of 4% or higher of one of the pregnancies being ectopic. The incidence of ectopic pregnancy among women presenting to the ED with vaginal bleeding or pain in the first trimester is consistently approximately 10%, but may be as high as 16%.20

Pathophysiology

Implantation of the fertilized ovum occurs approximately 8 or 9 days after ovulation. Risk factors for an abnormal site of implantation include prior tubal infection (50% of cases), anatomic abnormalities of the fallopian tubes, assisted reproduction (especially multiple embryo transfers), and abnormal endometrium (host factors). These result in failure of the embryo to implant in the endometrium. The risk of ectopic pregnancy increases approximately threefold after a patient has had pelvic inflammatory disease (PID). In recent studies, 25% of patients with ectopic pregnancies were found to have had tubal surgery, including tubal sterilization or removal of ectopic pregnancy.22 If the patient is currently using an intrauterine device (IUD), increased risk can occur from a complicating PID or from failure of the IUD to prevent pregnancy while preventing endometrial implantation. All forms of contraception, except the IUD and tubal sterilization, decrease the incidence of ectopic pregnancy. After an ectopic pregnancy, the risk of a subsequent ectopic pregnancy can be as high as 22%, depending on the characteristics and treatment of the ectopic pregnancy (eg, location of implantation, surgical vs. medical management; Box 178.2).22

When abnormal implantation occurs in the fallopian tubes, on the ovaries, or in the cervix, the pregnancy usually grows at a less than normal rate, which can result in abnormally low or declining hCG production. Even if exceedingly low, there is no value in using a single hCG measurement to exclude the diagnosis of ectopic pregnancy. Blood leaks intermittently through the tubal wall or out the fimbrial ends, with spillage into the peritoneal cavity. Bleeding and other symptoms are usually intermittent. Three outcomes are possible—spontaneous involution of the
Risk Factors for Ectopic Pregnancy

- Tubal surgery (for tubal sterilization or ectopic pregnancy)
- Pelvic inflammatory disease
- Smoking
- Advanced age
- Prior spontaneous abortion
- Medically induced abortion
- History of infertility
- Intrauterine device

Clinical Features

The classic clinical picture of ectopic pregnancy is a history of delayed menses, followed by abdominal pain and vaginal bleeding in a patient with known risk factors. Unfortunately, this history is neither sensitive nor specific. Risk factors for ectopic pregnancy are absent in almost half of patients. Of patients with symptomatic ectopic pregnancy, 15% to 20% have not missed a menstrual period, and occasionally the patient has no history of vaginal bleeding. Abdominal pain is usually severe, peritoneal in nature, and constant. Shoulder pain implies free fluid in the peritoneal cavity and is suggestive of an ectopic pregnancy with significant hemorrhage. The pain of ectopic pregnancy can also be crampy, intermittent, or even absent.

The physical findings in ectopic pregnancy are likewise variable. Vaginal bleeding, uterine or adnexal tenderness, or both in the patient with a positive pregnancy test result should trigger consideration of ectopic pregnancy. Tachycardia is not always present, even with significant hemoperitoneum; the hemoglobin level is usually normal, and hypotension may be seen. The presence of peritoneal signs, cervical motion tenderness, or lateral or bilateral abdominal or pelvic tenderness indicates an increased likelihood of ectopic pregnancy. If significant peritoneal irritation is present, pain can preclude an accurate bimanual examination. Adnexal masses are felt in only 10% to 20% of patients with ectopic pregnancy. Vaginal bleeding is often mild. Heavy bleeding with clots or tissue usually suggests a threatened or incomplete miscarriage, although the patient with an ectopic pregnancy who has decreasing hormonal levels may experience endometrial sloughing, which can be mistaken for passage of fetal tissue. Passed tissue should be examined, as with cases of miscarriage, in tap water or saline (or under low-power microscopy). Unless fetal parts or chorionic villi are seen, ectopic pregnancy should not be excluded in the patient with bleeding or passage of tissue.

Diagnostic Testing

Because the history and physical examination of the patient with ectopic pregnancy are insensitive and nonspecific, ancillary studies are essential to locate the pregnancy in any patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result. Technologic advances have allowed accurate detection and exclusion of ectopic pregnancy in the assessment of the woman with first-trimester vaginal bleeding or pelvic pain. Ultrasonography and hormonal assays are the most commonly used ancillary tests. Laparoscopy may be the most efficient diagnostic tool in the hemodynamically unstable patient.

Ultrasoundography. Ultrasonography is the primary method used to locate early gestation, establish gestational age, and assess fetal viability. Transabdominal ultrasonography is most useful for identification of IUPs with fetal cardiac activity and exclusion of ectopic pregnancy, except in patients at high risk for heterotopic pregnancy because of infertility procedures. Transvaginal ultrasonography is more sensitive, recognizes IUP earlier than transabdominal ultrasonography, and is diagnostic in up to 80% of stable patients presenting in the first trimester. In one series of more than 1000 pelvic ultrasound examinations, 53% of indeterminate ultrasound studies resulted in a diagnosis of embryonic demise, 15% were ectopic pregnancies, and only 29% had an IUP. However, correlation of sonographic results with quantitative hCG measurements can add to the predictive value. With hCG levels less than 1000 mIU/mL, the risk of ectopic pregnancy increases fourfold, and ultrasonography is still diagnostic in approximately one-third of these patients with ectopic pregnancy. Normal pregnancy is unlikely if no gestational sac is seen by transvaginal ultrasonography with an hCG level higher than 1000 to 2000 mIU/mL, depending on the institution’s discriminatory zone, but the differential diagnosis includes miscarriage and ectopic pregnancy. Unfortunately, levels of approximately 1500 mIU/mL develop in only approximately 50% of patients with ectopic pregnancies (see Table 178.1).

Indeterminate sonograms, which demonstrate neither an IUP nor extraterine findings suggestive of ectopic pregnancy, occur in approximately 20% of ED evaluations of women with...
first-trimester bleeding or pain. Ectopic pregnancy is more likely among this subgroup with indeterminate sonograms if the hCG level is less than 1000 mIU/mL and the uterus is empty. Endometrial debris and fluid in the uterus do not exclude ectopic pregnancy.25

Use of bedside ultrasonography in the ED for the diagnosis of IUP and exclusion of ectopic pregnancy has shown good sensitivity and negative predictive value in ruling out ectopic pregnancy, but it requires significant operator training.26-28 In addition to operator-based limitations, the use of ultrasonography is also limited by device availability and quality.

**Hormonal Assays.** Quantitative hCG levels serve two primary functions—serial levels can be used in the stable patient who can be observed as an outpatient, and a single level can be correlated with sonographic results for improved interpretation. Serum hCG levels normally double every 1.8 to 3 days for the first 6 or 7 weeks of pregnancy, beginning 8 or 9 days after ovulation. An initial quantitative level can be measured at the time of the ED visit, particularly if the sonogram is indeterminate or gestational age is estimated as less than 6 weeks. A repeated level should be measured 48 to 72 hours later. Levels that fall or rise slowly are associated with abnormal pregnancy, intrauterine or ectopic. Of women with an ectopic pregnancy, 21% in one series had an initial rise in hCG at a rate consistent with an IUP.

Single quantitative hCG levels can also be useful in conjunction with ultrasonography; normal IUPs should be visible transvaginally at 1000 to 2000 mIU/mL hCG or higher (see Table 178.1). A benign course for ectopic pregnancy cannot be assumed with low hCG levels. Ruptured ectopic pregnancies requiring surgery have been reported with very low or absent levels of hCG.

Serum progesterone levels have been studied as an additional or alternative marker to determine which patients need further
evaluation and follow-up for possible ectopic pregnancy. The progesterone level rises earlier than hCG level in normal pregnancy and plateaus with levels higher than 20 ng/mL, so measurement of serial levels over time is not necessary. Levels below 5 ng/mL exclude viable IUP—with rare exceptions—and could be useful when the hCG levels are low, ultrasonography is indeterminate, and the emergency clinician is considering D&C or laparoscopy. The ability of a progesterone level to differentiate ectopic pregnancy from a failed IUP is limited, and it is not a standard tool for ED evaluation.

Other Studies. Dilation and evacuation can be used in patients without a viable IUP or ectopic pregnancy on ultrasonography to differentiate intrauterine miscarriage from ectopic pregnancy. Identification of chorionic villi in endometrial samples is seen in approximately 70% of patients and excludes ectopic pregnancy, except in patients undergoing assisted reproduction. Identification of chorionic villi can be made, even in 50% of women with an empty uterus on ultrasonography, and limits the need for laparoscopy to exclude ectopic pregnancy in this population.

Although it is invasive, laparoscopy is extremely accurate as a diagnostic (and therapeutic) procedure for possible ectopic pregnancy. It is the diagnostic treatment of choice in the unstable first-trimester patient with peritoneal signs and is also indicated in patients with significant peritoneal fluid or an ectopic gestation in the pelvic cavity. Medical alternatives for the management of ectopic pregnancy have resulted in decreased indications for laparoscopy in stable patients.

Fig. 178.5. Ultrasonogram showing a gestational pseudosac. (Courtesy Dr. Mary Ann Edens.)

Differential Diagnosis

The spectrum of clinical presentations in ectopic pregnancy is wide, so the differential diagnosis includes essentially all first-trimester complications. Threatened miscarriage, the most common alternative diagnosis, can be recognized by sonographic evidence of an IUP, healthy or failed. Hypovolemia may be seen, particularly in incomplete miscarriage, but hypotension without significant vaginal hemorrhage is highly suggestive of ectopic pregnancy. Identification of fetal parts or chorionic villi in tissue expelled or obtained during D&C is useful to confirm a complication of IUP, although this is not sufficient to exclude ectopic pregnancy in the patient with an increased risk of heterotopic gestation, such as the patient undergoing assisted reproduction treatment.

A ruptured corpus luteum cyst should also be considered in the patient who has first-trimester bleeding associated with peritoneal pain or irritation. The corpus luteum normally supports the pregnancy during the first 7 or 8 weeks. Rupture causes pelvic pain and peritoneal irritation. Ultrasonography is helpful if it reveals an IUP (except in patients with in vitro fertilization). During early gestation, when ultrasonography is nondiagnostic, free fluid is usually visible by ultrasonography, and serial observation may be required (see Fig. 178.4). If the patient is unstable, especially if an IUP cannot be identified by ultrasonography, laparoscopy or, rarely, laparotomy may be required to differentiate between the two conditions.

Management

Classically, approximately 20% of women with ectopic pregnancies manifest signs and symptoms warranting immediate intervention. This includes patients with significant hypovolemia, large amounts of peritoneal fluid, or an open cervical os. For patients with significant signs of hypovolemia, rapid volume resuscitation should be instituted with intravenous (IV) fluids and blood products as necessary, and a baseline hemoglobin level and type and crossmatch should be obtained. A D&C or evacuation procedure with examination of the endometrial contents for products of conception can be performed urgently in the unstable patient with an open cervical os.

If the patient remains unstable, immediate surgery is warranted. Laparoscopy may be indicated for patients who stabilize with treatment or those who are hemodynamically stable but exhibit significant peritoneal signs on abdominal examination. One study has reported that identification of free fluid in Morrison’s pouch on bedside ultrasonography predicts the need for operative intervention in most cases in patients with suspected ectopic pregnancies. All patients with ectopic pregnancy who are Rh-negative should be given Rh immune globulin, 50 µg intramuscularly.

Most patients who seek treatment for bleeding or pain during the first trimester of pregnancy are stable. In these patients, the goal should be to exclude ectopic pregnancy in a timely manner. In the patient with significant pain by history or examination or significant risk factors for ectopic pregnancy, ultrasonography should be performed before discharge. If the results are indeterminate, a quantitative hCG level may be helpful in determining the patient’s risk for ectopic pregnancy.

In low-risk patients with only minor symptoms or bleeding, ectopic pregnancy is still a possibility. Two general outpatient approaches can be considered. In most institutions, ultrasonography is the initial screening tool (Fig. 178.6). If an IUP is not seen, quantitative hCG levels help risk stratify these patients. In all cases, if the patient is discharged, careful instructions are given for symptoms that would require her earlier return (ectopic precautions). An alternative strategy uses hCG levels first. However, waiting times for the serum assay can increase ED length of stay. In addition, ultrasonography is usually diagnostic of IUP or ectopic pregnancy, even if the hCG level is less than 1000 mIU/mL. In most cases, the initial sonogram provides more rapid and accurate information.

A significant minority of patients have indeterminate sonographic results and hCG levels below 1000 mIU/mL. When the hCG levels never rise to the discriminatory zone, the differential diagnosis includes intrauterine fetal demise and ectopic pregnancy. Early D&C with identification of the products of conception can be useful in the patient with nonrising hCG levels to detect chorionic villi and confirm a failed IUP or strongly suggest ectopic pregnancy. Alternatively, hCG levels can be followed until they reach zero, particularly if initial levels are low.
Stable first-trimester patient with vaginal bleeding or pain

Sonography (TVS or TAS) at time of visit or within 48 hours

Ectopic pregnancy
Obtain quantitative hCG. Consult OB. Consider methotrexate therapy versus surgery.

Indeterminate
Obtain quantitative hCG. Assess clinical acuity.

Intrauterine pregnancy
Follow-up with OB
Threatened miscarriage precautions

>1500 hCG
• Phone consult with OB.
• Follow serial hCGs to determine ectopic pregnancy or miscarriage.

<1500 hCG
If clinically benign:
• Phone consult with OB.
• Follow serial hCGs.
• Repeat U/S in 2 days or when hCG is >3000 for TVS.

Although laparotomy may be required for patients who have an ectopic pregnancy, an increasing number of surgeries are being performed through the laparoscope. Salpingostomy is preferred to salpingectomy if the patient is stable and the procedure is technically feasible. Overall, the advent of transvaginal ultrasonography has resulted in a decreased number of surgeries and a trend toward nonoperative management.

Medical management is a safe and cost-effective treatment for the stable patient with minimal symptoms, especially when future fertility is desired.

Methotrexate is the drug most commonly used to treat early ectopic pregnancy. It interferes with fetal DNA synthesis and causes destruction of rapidly dividing fetal cells and involution of the pregnancy. Medical treatment is used most often for patients who are hemodynamically stable, with a tubal mass smaller than 3.5 cm in diameter, no fetal cardiac activity, and no sonographic evidence of rupture. Although there is no agreed on hCG cutoff for single-dose methotrexate, studies have suggested that increasing hCG levels are significantly correlated with methotrexate failure. Medical therapies are associated with an 85% to 93% success rate, with no significant difference between single- and multiple-dose protocols. Pelvic pain is common in patients receiving methotrexate (60%), even when it is used successfully. Indications of methotrexate failure and need for rescue surgery include decreasing hemoglobin levels, significant pelvic fluid, and unstable vital signs. All patients receiving methotrexate require close follow-up until the hCG level reaches 0, which may take 2 or 3 months.

Molar Pregnancy
Molar pregnancy, also known as a hydatidiform mole, comprises a spectrum of diseases characterized by disordered proliferation of chorionic villi. In the absence of fetal tissue, the pregnancy is termed a complete hydatidiform mole. Complete moles are caused by the fertilization of an ovum without maternal DNA and the subsequent duplication of the haploid genome. The term incomplete mole refers to a mole that is caused by the fertilization of a normal ovum by two sperm. The duplication of the triploid karyotype causes some fetal tissue to be present, along with focal trophoblastic hyperplasia. In approximately 19% of molar pregnancies, neoplastic gestational disease develops, with persistence of molar tissue after the pregnancy has been evacuated. Metastatic disease can develop, requiring chemotherapy and intensive oncologic management.

Early molar pregnancy is usually not clinically apparent. The most well-described risk factor for the development of a molar pregnancy is extreme maternal age. Many patients present with abdominal pain, nausea and vomiting, or vaginal bleeding, and it may be difficult to differentiate these patients from those with threatened miscarriage or ectopic pregnancy by historical features alone. Patients sometimes seek treatment for apparent persistent hyperemesis gravidarum from high circulating levels of hCG, bleeding or intermittent bloody discharge, or respiratory distress; failure to hear fetal heart tones during the second trimester is the usual initial clue to diagnosis. If molar pregnancy spontaneously aborts, it is usually in the second trimester (before 20 weeks), and the patient or physician may note the passage of grapelike hydatid vesicles. Uterine size is larger than expected by date (by >4 weeks) in approximately 30% to 40% of patients. Theca lutein cysts may be present on the ovaries as a result of excessive hormonal stimulation, and torsion of affected ovaries can be seen.

The characteristic sonographic appearance of hydropic vesicles within the uterus, described as a snowstorm appearance, is highly suggestive of a diagnosis of molar pregnancy (Fig. 178.7). Alternatively, cystic changes are seen in partial molar pregnancies. In some cases, a partial molar pregnancy is detected only on pathologic examination of abortion specimens. Complications of molar pregnancy include preeclampsia or eclampsia, which can develop before 24 weeks of gestation, respiratory failure or distress from pulmonary embolization of trophoblastic cells, hyperemesis gravidarum, and significant uterine bleeding, acute or chronic. Ultrasonography usually provides the diagnosis of a complete molar pregnancy in the second-trimester patient who has “threatened miscarriage” or during sonographic assessment for fetal well-being and size. However, ultrasonography is only 58% sensitive, and diagnosis of a partial mole is made in 17% of cases. Up to two-thirds of molar pregnancies are diagnosed by pathologic specimens after miscarriage.

Following evacuation of a molar pregnancy, patients must be monitored in the outpatient setting for trophoblastic sequelae. Patients are at increased risk of an invasive mole, a benign tumor that invades the uterine wall and metastasizes to the lungs or vagina, or choriocarcinoma, a malignant tumor that invades the uterine wall and metastasizes to the lungs, brain, and liver via the patient’s vasculature. Patients who present to the ED with complications of bleeding metastases are managed with a combination of chemotherapy, radiation, and surgery.

**COMPLICATIONS OF LATE PREGNANCY**

**Vaginal Bleeding in Later Pregnancy**

Bleeding during the second half of pregnancy occurs in approximately 4% of pregnancies. Only 20% of miscarriages occur after the first trimester, and the most important differential diagnoses after 12 to 14 weeks of gestation are abruptio placentae and placenta previa. The cause is often not determined, although occult marginal placental separations, which can be recognized only by placental inspection at delivery, are believed to come from a common source of bleeding above the cervix. Other causes of late
Abruptio Placentae

Abruptio placentae, or separation of the placenta from the uterine wall, is believed to account for approximately 30% of episodes of bleeding during the second half of pregnancy, 10% of preterm births, and 10% to 20% of perinatal deaths. Small subclinical or marginal separations may go undetected until the placenta is examined at delivery and probably account for many of the other self-limited episodes of bleeding for which no diagnosis is made. In cases of nontraumatic abruptio placentae, apparently spontaneous hemorrhage into the decidua basalis occurs, causing separation and compression of the adjacent placenta. Small amounts of bleeding may be asymptomatic and remain undetected until delivery. In other cases, the hematoma expands and extends the dissection. Bleeding may be concealed or may be clinically apparent if dissection occurs along the uterine wall and through the cervix. Placental separation may be acute or may be an indolent problem throughout late pregnancy.

Abruptio placentae is most clearly associated with maternal hypertension and preeclampsia. It is also more common with maternal age younger than 20 or 35 years of age or older, parity of three or more, unexplained infertility, history of smoking, thrombophilia, prior miscarriage, prior abruptio placentae, and cocaine use. Placental separation can also be associated with blunt trauma to the abdomen. In such cases, the cause appears to be shearing of a nonelastic placenta from the easily distorted elastic uterine wall at the time of traumatic impact. Women who reported physical violence during pregnancy were found to be twice as likely as women who did not report violence to have an abruption.

Clinical Features. Vaginal bleeding occurs in 70% of patients with abruptio placentae. Blood is characteristically dark and the amount is often insignificant, although the mother may have hemodynamic evidence of significant blood loss. Uterine tenderness or pain is seen in approximately two-thirds of women; uterine irritability or contractions are seen in one-third. With significant placental separation, fetal distress occurs, and the maternal coagulation cascade may be triggered, causing disseminated intravascular coagulation (DIC).

There is a wide spectrum of severity of symptoms and risk in placental separation. Up to 20% of women will have no pain or vaginal bleeding. Assessment is generally based on clinical features, coagulation parameters, and signs of fetal distress. Slight vaginal bleeding, little or no uterine irritability, absence of signs of fetal distress, and normal coagulation characterize mild abruption. As the separation becomes more extensive, it is associated with severe symptoms and increased risk of maternal and fetal complications.
with more vaginal bleeding (or hidden maternal blood loss), increased uterine irritability, with or without tetanic contractions, declining fibrinogen levels, and evidence of fetal distress and maternal tachycardia. In severe abruptio placentae (15% of cases), the uterus is tetanically contracted and very painful, maternal hypotension results from visible or concealed uterine blood loss, fibrinogen levels are less than 150 mg/dL, and fetal death can occur. Ultrasonography is insensitive in the diagnosis of abruptio placentae, often because the echogenicity of fresh blood is so similar to that of the placenta. Symptomatic or even fetus-threatening abruption can occur in the presence of a normal sonogram. 

Fetal distress and death occur in approximately 15% of patients with abruptio placentae by interruption of placental blood and oxygen flow. Risk of fetal death increases in proportion to the percentage of the placental surface involved and rapidity of separation. Fetal distress may result from the loss of placental blood flow, associated maternal hemorrhage (into the uterine cavity or externally), increased uterine tone, or resultant DIC. Maternal death can result, usually from coagulopathy or exsanguination. Fetomaternal transfusion occurs in a significant minority of patients. Placental separation also predisposes the mother to amniotic fluid embolism.

**Differential Diagnosis.** The main alternative diagnosis in the woman with late-pregnancy bleeding is placenta previa, which is usually associated with painless, bright red bleeding and is excluded with ultrasonography. Lower genital tract or rectal lesions and bloody show (blood-tinged cervical mucous plug) are also considerations. In the patient with abdominal pain but no vaginal bleeding, abruptio placentae with concealed hemorrhage must be distinguished from other causes of abdominal pain in later pregnancy—complications of preeclampsia, pyelonephritis, various liver diseases, gallbladder disease, appendicitis, and ovarian torsion. Uterine irritability caused by abruptio placentae can also be confused with early labor; in one series, almost 25% of patients were misdiagnosed as having premature labor until fetal distress occurred. If the patient has acute catastrophic hypotension, amniotic fluid embolus, with or without abruptio placentae, and uterine rupture must be considered.

**Placenta Previa**

Placenta previa, or implantation of the placenta over the cervical os, is the other major cause of bleeding episodes during the second half of pregnancy. The risk of placenta previa is increased with maternal age, smoking, multiparity, cesarean section, prior miscarriage or induced abortions, and preterm labor. 

Bleeding occurs when marginal placental vessels implanted in the lower uterine segment are torn, either as the lower uterine wall elongates or with cervical dilation near the time of delivery. Early bleeding episodes tend to be self-limited unless separation of the placental margin is aggravated by iatrogenic cervical probing or the onset of labor.

**Clinical Features.** Painless, fresh vaginal bleeding is the most common symptom of placenta previa. In approximately 20% of cases, some degree of uterine irritability is present, but this is generally minor. Vaginal examination usually reveals bright red blood from the cervical os. All patients with painless, second-trimester vaginal bleeding should be assumed to have placenta previa until proven otherwise. Digital or instrumental probing of the cervix should be avoided until the diagnosis is excluded via ultrasound. Injudicious vaginal examination can precipitate severe hemorrhage in the patient with an asymptomatic or minimally symptomatic placenta previa. Speculum examination of the vagina and cervix should be performed only in those settings in which obstetric consultation is not readily available. It should be limited to an atraumatic partial speculum insertion to identify whether the bleeding is coming from the cervical os (and a presumed placenta previa), hemorrhoids, or a vaginal lesion that might not require urgent management.

Most cases of placenta previa identified during the midtrimester resolve by the time of delivery as the lower uterine segment elongates and the placenta no longer overlaps the cervical os. Central or total previa, which occurs in approximately 20% of cases, can, however, cause severe hemorrhage, with the risk of exsanguination for the fetus and mother.

**Diagnostic Testing.** Ultrasonography is the diagnostic procedure of choice for localization of the placenta and diagnosis of placenta previa. Accuracy is excellent, but visualization of the placenta and of the internal cervical os is required. The bladder should be emptied before examination for suspected placenta previa to avoid overdiagnosis of placenta previa. Transvaginal ultrasonography is safe and even more accurate for visualization of the relationships between the placenta and internal os.

**Management.** Patients who experience vaginal bleeding during late pregnancy should have immediate obstetric consultation and arrangements for safe transfer to an appropriate obstetric facility. Initial management consists of maternal stabilization, with establishment of two large-bore IV lines and fluid resuscitation, as well as continuous fetal monitoring, if available. A baseline hemoglobin level should be determined, and blood should be sent for type and crossmatch. Baseline coagulation studies, including platelet count, prothrombin time, and partial thromboplastin time, should be performed, and the fibrinogen level and presence of fibrin split products should be determined. The normal fibrinogen level in pregnancy is 400 to 450 mg/dL; values below 300 mg/dL indicate significant consumption of coagulation factors.

Blood loss requiring transfusion can occur in patients with placenta previa or abruptio placentae. Fresh-frozen plasma or fresh whole blood may be needed because of the coagulopathy associated with significant abruptio placentae. Fetomaternal hemorrhage can occur with abruption. If the Rh-negative patient has not yet received her routine Rh immune globulin prophylaxis at 28 weeks, 300 µg of Rh immune globulin should be administered within 72 hours. Transfer to the obstetric unit should be expedited if the patient is stable, or it should be done after initiation of resuscitation if she is unstable. If transfer to another hospital is required, a high-risk transfer team should be used if bleeding is significant or the fetus is in distress. Although the bleeding source may not be identified or may be relatively benign, assessment is best accomplished by obstetricians who are accustomed to the evaluation of late-pregnancy complications and who can perform emergent cesarean section, if needed.

In the obstetrics unit, fetal monitoring is continued. Ultrasonography is used primarily to locate the placenta and diagnose placenta previa, but it may not be reliable in confirming the diagnosis of abruptio placentae. On occasion, subplacental hemorrhages of abruptio placentae can be seen, and changes in size of the collection can be monitored. If evidence of placenta previa is absent or equivocal, a vaginal examination is performed in the delivery suite, where an emergency cesarean section can be performed if uncontrolled bleeding is encountered.

Patients who have significant abruptio placentae may require early delivery—vaginal or surgical, depending on fetal status. If placenta previa is diagnosed or if abruptio placentae is considered mild, the patient is admitted for close monitoring. The goal is to support the patient, ideally until fetal maturity is demonstrated and a successful delivery can be accomplished.
Pregnancy-Induced Hypertension (Preeclampsia and Eclampsia)

Hypertension is observed in up to 8% of pregnancies and is generally divided into several categories:40

- Gestational hypertension occurs during pregnancy, resolves during the postpartum period, and is recognized by a new blood pressure reading of 140/90 mm Hg or higher.
- Preeclampsia is gestational hypertension with proteinuria (>300 mg/24 hr).
- Eclampsia is the occurrence of seizures in the patient with signs of preeclampsia. Progression of preeclampsia to eclampsia is unpredictable and can occur rapidly.
- Pregnancy-aggravated hypertension is chronic hypertension, with superimposed preeclampsia or eclampsia.
- Chronic or coincidental hypertension is present before pregnancy or persists more than 6 weeks postpartum.40

Approximately 2% to 7% of pregnancies are complicated by pregnancy-induced hypertension. The incidence of actual eclampsia has progressively declined but is still one of the major causes of maternal mortality. The risk of pregnancy-induced hypertension is greatest in women younger than 20 years, primigravidas, those with twin or molar pregnancies, those with hypercholesterolemia, pregestational diabetes, or obesity, and those with a family history of pregnancy-induced hypertension.40

Pathophysiology

Gestational hypertension or preeclampsia is a vasospastic disease of unknown cause unique to pregnant women. Vasospasm, ischemia, and thrombosis associated with preeclamptic changes cause injury to maternal organs, placental infarction and abruption, and fetal death from hypoxia and prematurity. The cause of eclampsia is unknown, but recent studies have centered on vascular responsiveness to endogenous vasopressors in the preeclamptic woman. Vascular responsiveness is normally depressed during pregnancy, which is a high-output, low-resistance state. Gestational hypertension is characterized by an even greater elevation in cardiac output, followed by an abnormally high peripheral resistance as clinical manifestations of the disease develop. In patients with preeclampsia, the cardiac output eventually drops as peripheral resistance rises.41 The cause of these changes is not known, but endothelial dysfunction is purported to release vasoactive mediators and result in vasoconstriction. Antiplatelet agents during pregnancy have been reported to reduce the risk of development of preeclampsia, supporting the premise of an imbalance between levels of thromboxane and prostacyclin in preeclampsia.42

The vasospastic effects of gestational hypertension and preeclampsia are protean. The intravascular volume is lower than in normal pregnancy, central venous pressures are normal, and capillary wedge pressures are variable. Liver effects are believed to be due to hepatocellular necrosis and edema resulting from vasospasm. Renal injury causes proteinuria and may result in decreased glomerular filtration. Microangiopathic hemolysis may result from vasospasm, causing thrombocytopenia. Central nervous system (CNS) effects include microvascular thrombosis and hemorrhage, as well as focal edema and hyperemia.43

Clinical Features

**Signs and Symptoms.** The patient with gestational hypertension has mild systolic or diastolic blood pressure elevation, no proteinuria, and no evidence of organ damage. Mental status assessment, testing of reflexes, abdominal examination, liver function studies, and coagulation studies yield normal results. Preeclampsia is associated with kidney changes and, in severe cases, other end-organ symptoms. Edema is often difficult to assess because pregnancy is normally associated with excess extracellular fluid and dependent edema, and it is no longer used as a criterion for preeclampsia. Proteinuria (300 mg/24 hr) is variable at any given time and may not be detectable in a random urine specimen.44

In cases of severe preeclampsia, the diastolic blood pressure can exceed 110 mm Hg, proteinuria is more severe, and there is evidence of vasospastic effects in various end organs. CNS effects commonly include headache or visual disturbances. Thrombocytopenia may be present, liver function test findings may be elevated, and the liver is often tender. Renal dysfunction may be indicated by oliguria and elevated creatinine levels in addition to proteinuria.

Complications

The HELLP syndrome, a particularly severe form of preeclampsia that develops in 5% to 10% of women who have preeclamptic symptoms, is characterized by hemolysis, elevated liver enzyme levels (alanine transaminase [ALT] and aspartate transaminase [AST] > 70 U/L), and low platelet count (<100,000/mL). Prothrombin time, partial thromboplastin time, and fibrinogen level are normal, and blood studies reveal microangiopathic hemolytic anemia. Other complications of preeclampsia include spontaneous hepatic and splenic hemorrhage and abruptio placentae.

The most dangerous complication is eclampsia, which is the occurrence of seizures or coma in the setting of signs and symptoms of preeclampsia. Warning signs for the development of eclampsia include headache, nausea and vomiting, and visual disturbances. Elevated total leukocyte count, and creatinine and AST levels are also predictive of increased morbidity for the patient with severe preeclampsia. Particularly in early eclampsia before 32 weeks of gestation, seizures may develop abruptly, and hypertension may not be associated with edema or proteinuria.45 In postpartum women who have eclampsia, more than half (55%) have not been previously diagnosed with preeclampsia, and patients may present with headache, vision changes, elevated blood pressure, and/or seizures up to 4 weeks after delivery.46 After 48 hours postpartum and without predelivery signs of preeclampsia, other diagnoses, such as intracranial hemorrhage, should be considered. Maternal complications of eclampsia include permanent CNS damage from recurrent seizures or intracranial bleeding, renal insufficiency, and death.

The maternal mortality rate from eclampsia has been reduced to less than 1% with modern management. Perinatal mortality has also decreased, although it remains at 4% to 8%.47 Causes of neonatal death include placental infarcts, intraterine growth retardation, and abruptio placentae. In addition, fetal hypoxia from maternal seizures and the complications of premature delivery contribute significantly to fetal morbidity and mortality.

Diagnostic Testing

The patient who has severe preeclampsia should have an IV line and fetal monitoring initiated. Blood testing should include complete blood cell count, renal function studies, liver function tests, platelet count, and coagulation profile. A baseline magnesium level should also be determined. In the patient with actual seizures, the serum glucose concentration should be determined. If a history of preeclampsia is not obtained or the symptoms are refractory to magnesium sulfate therapy, a computed tomography (CT) scan of the head should be performed to exclude cerebral venous thrombosis or an intracranial bleed, either of which can occur in pregnancy—with or without pregnancy-induced hypertension—and may require specific treatment. CT scan abnormalities can be seen in 50% of patients with eclampsia. Patchy hemorrhage and microinfarcts of the cortex are
characteristic and may be due to loss of cerebral autoregulation in patients with severe pregnancy-related hypertension. Diffuse cerebral edema can also be seen.

**Differential Diagnosis**

Peripheral edema is common in normal pregnancy, and it may be difficult to differentiate normal edema from that of early pre-eclampsia. Differentiation of gestational hypertension from pre-existent hypertension is often impossible if no record of normal blood pressure is available. Seizures during pregnancy may be due to epilepsy as well as other intracranial catastrophes, such as thrombosis or hemorrhage.

**Management**

The management of patients with mild pre eclampsia includes documentation of blood pressure and reflexes, weight, and testing to ensure normal end-organ function. Accurate determination of gestational age by ultrasonography is needed to allow optimal management if symptoms progress. Limitation of physical activities, including bed rest, is the only demonstrated means of reducing blood pressure and allowing the pregnancy to be sustained longer. Definitive treatment is delivery of the fetus, although expectant management is standard in women at less than 34 weeks of gestation. Arrangement for close follow-up is important for patients who are not hospitalized.

Hospitalization is usually required for patients with sustained hypertension above 140/90 mm Hg and signs of severe pre-eclampsia. Baseline laboratory studies should be carried out to identify end-organ effects in the liver, kidney, and hematologic systems. Both diuresis and antihypertensive therapy have been remarkably unsuccessful in improving fetal outcome and/or prolonging pregnancy. Admission does, however, allow the obstetrician to assess fetal age and well-being accurately, maternal organ function, and effect of bed rest on blood pressure before the optimal timing of delivery is decided.

Fulminant or severe preeclampsia, with marked blood pressure elevation (≥160/110 mm Hg) associated with epigastric or liver tenderness, visual disturbance, or severe headache, is managed in the same way as eclampsia (Box 178.4). The goal is prevention of seizures and permanent damage to maternal organs. Magnesium sulfate is given for seizure prophylaxis.

**BOX 178.4**

**Management of Eclampsia and Severe Preeclampsia**

Control seizures with magnesium sulfate.

Control hypertension after seizure control if diastolic blood pressure >105 mm Hg.

Obtain initial laboratory studies to assess organ injury:
- Complete blood count and platelet count
- Liver function tests
- Blood urea nitrogen, creatinine
- Monitor urine output; maintain at <25 mL/hr.
- Limit intravenous fluid administration unless significant losses occur.
- Avoid diuretics and hyperosmotic agents.
- Perform a computed tomography scan of the head if consciousness is decreased or seizures persist, lateralizing signs are present, or there are other concerns.
- Initiate steps to delivery.

Seizures and coma are the hallmarks of eclampsia, the ultimate consequence of preeclampsia. As in all seizure patients, hypoglycemia, drug overdose, and other causes of seizures should be excluded with appropriate tests. Eclamptic seizures are controlled in almost all patients by adequate doses of magnesium sulfate, although the mechanism of action remains elusive. Magnesium has little antihypertensive effect but is the most effective anticonvulsant, preventing recurrent seizures while maintaining uterine and fetal blood flow. The goals of magnesium sulfate therapy are to terminate ongoing seizures and prevent further seizures. An IV loading dose of 4 g magnesium, followed by 2 g/hr IV, is recommended. Magnesium administration should be accompanied by clinical observation for loss of reflexes (which occurs at ≥10 mg/dL) or respiratory depression (which occurs at levels of 12 mg/dL, although actual serum magnesium levels are rarely monitored). The infusion should be stopped if signs of hypermagnesemia are seen, because such patients may require assisted ventilation. IV calcium gluconate, 1 g given slowly, will reverse the adverse effects of hypermagnesemia.

Despite ongoing controversy, the familiarity with magnesium sulfate and its physiologic advantages to the fetus, wide margin of safety, and high success rate in controlling seizures make it the first-line drug in patients with eclampsia. A Cochrane review has found that magnesium sulfate is more effective than other anticonvulsants and diazepam for prophylaxis against or treatment of eclamptic seizures, more than halving the risk. If seizures persist after the recommended doses of magnesium sulfate have been administered, diazepam or phenytoin may be given as alternative regimens in conjunction with obstetric consultation, and a careful search for other causes of seizures (eg, hypoglycemia and intracranial bleed) should be instituted.

Although magnesium sulfate is not a direct antihypertensive, the hypertension associated with eclampsia is often controlled adequately by stoppage of the seizures. Rapid lowering of blood pressure can result in uterine hypoperfusion, so specific antihypertensive treatment is initiated only if the diastolic blood pressure remains above 105 mm Hg after control of seizures. Many patients do not require specific antihypertensive treatment after treatment with magnesium sulfate. The antihypertensive used most often by obstetricians is hydralazine, 5 mg IV, with repeated doses of 5 to 10 mg IV every 20 minutes as needed to keep the diastolic blood pressure below 105 mm Hg. Nimodipine and labetalol have also been reported to be safe and effective, although they are less widely used. Other antihypertensive agents have not been well studied in this population because there are specific risks to uncontrolled lowering of blood pressure and loss of uteroplacental blood flow.

Although total body water in the eclamptic patient is excessive, intravascular volume is contracted, and the eclamptic patient is sensitive to further volume changes. Hypovolemia results in decreased uterine perfusion. Thus, diuretics and hyperosmotic agents should be avoided in these patients. Invasive monitoring has demonstrated that vasospasm is not reversed with IV fluid administration. Rather, excessive IV fluids increase extravascular fluid stores that are difficult to mobilize postpartum, resulting in a higher incidence of pulmonary edema in patients treated aggressively with fluid therapy. Invasive pulmonary artery pressure monitoring may be required for accurate fluid management in the eclamptic patient.

**Amniotic Fluid Embolus**

Amniotic fluid embolus is the release of amniotic fluid into the maternal circulation during intense uterine contractions or uterine manipulation at areas of placental separation from the uterine decidua basalis (abruptio placentae), triggering a rapidly fatal, anaphylactoid-type maternal response. Although amniotic...
fluid embolus usually occurs during labor, with the maternal mortality rate at 25% or higher, it can also occur after induced abortions and miscarriages and spontaneously during the second and third trimesters. Amniotic fluid embolus can also occur after amniocentesis or in association with abruptio placentae after abdominal trauma. Although it is a rare syndrome, amniotic fluid embolus is the leading cause of cardiovascular collapse during labor.46

Clinical Features

Amniotic fluid embolus should be suspected during the second or third trimester of pregnancy, particularly in the setting of uterine manipulation or contraction, when a patient experiences sudden hypotension, hypoxia, and coagulopathy. The embolization of amniotic fluid and the particulate matter suspended in it triggers a profound immunologic response when it enters the maternal circulation. The list of proposed mediators is extensive and includes histamine, endothelin, and leukotrienes.46 In survivors, DIC, acute respiratory distress syndrome, and left ventricular dysfunction develop. An initial seizure is seen in approximately 20% of patients. Bleeding diathesis may be the initial sign in some women, and DIC occurs in approximately 50%.

Diagnostic Testing

When amniotic fluid embolus is suspected, a complete blood cell count, coagulation studies, arterial blood gas analysis, and chest radiograph should be obtained. Urine output should be monitored after urinary catheter placement. The diagnosis is usually made with certainty only at autopsy, with the finding of fetal hairs, squamous cells, and debris in the maternal circulation. Because squamous epithelial cells can be seen normally in the maternal pulmonary circulation, the typical clinical syndrome is also required for diagnosis.

Differential Diagnosis

Catastrophic pulmonary embolus, drug-induced anaphylaxis, and septic shock must be considered in the differential diagnosis. Seizures occur in patients with eclampsia, but hypertension rather than cardiovascular collapse is usually observed in that condition. Coagulopathy may be seen in patients with preeclampsia (HELLP syndrome), abruptio placentae, or other chronic coagulopathies seen in the nonpregnant patient.

Management

Amniotic fluid embolus is uncommon, so treatment recommendations are anecdotal and have been based on animal studies. The most helpful modalities appear to be high-flow oxygen, support of ventilation and oxygenation with intubation, aggressive fluid resuscitation, inotropic cardiovascular support, and anticipation and management of consumptive coagulopathy. Adequate treatment usually requires invasive hemodynamic monitoring in an intensive care unit.

Rh (Anti-D) Immunization in Pregnancy

Rh immunization occurs when an Rh-negative woman is exposed to Rh-positive fetal blood. Small numbers of fetal cells enter the maternal circulation spontaneously throughout pregnancy, but the maternal immune system is triggered only by significant loads of fetal cells, which can occur during the third trimester and at delivery. Sensitization occurs in up to 15% of Rh-negative women carrying Rh-positive fetuses. To prevent this, anti-D immune globulin (RhoGAM) is routinely administered to Rh-negative mothers—if the father is Rh positive or his status is unknown—at approximately the 28th week of gestation to protect the mother from spontaneous sensitization, which occurs during the third trimester. Transplacental hemorrhage can also occur during uterine manipulation, threatened miscarriage (even without fetal loss), spontaneous miscarriage, surgery for ectopic pregnancy, and amniocentesis, although the risk is not clear. Anti-D immune globulin should be administered when these events occur. A dose of 50 µg can be used if the patient is at less than 12 weeks of gestation, although many pharmacies carry only the 300-µg dose, which can also be given. After 12 weeks, a 300-µg dose should be given. The half-life of immune globulin is 24 days, and it needs to be administered within 72 hours of a sensitization event to prevent antibody development.

The Kleihauer-Betke test of maternal blood has been used to detect fetal cells in the maternal circulation. Unfortunately, the test is difficult to perform, not immediately available in most emergency laboratories, and only sensitive enough to detect 5 mL of fetal cells in the maternal circulation. Because only 0.1 mL of fetal cells is required to sensitize the mother, routine immune globulin administration has been recommended in situations likely to result in sensitization. Patients with third-trimester bleeding are not at increased risk of sensitization compared with patients with normal pregnancy. Thus, RhoGAM should be administered only if the patient did not receive her prophylactic dose at 28 weeks. In cases of significant blunt trauma to the uterus, the Kleihauer-Betke test should be ordered to detect the rare, large fetal transfusions that may require specific fetal blood therapy or administration of additional immune globulin to the mother. The standard dose (300 µg) is sufficient to prevent maternal immunization for fetal transfusions of up to 15 mL of red blood cells or 30 mL of whole blood.

MEDICAL AND SURGICAL PROBLEMS IN THE PREGNANT PATIENT

Clinicians should be aware of a variety of illnesses, related and unrelated to pregnancy, that may have altered symptoms, risk, and treatment in the pregnant patient (Tables 178.2 and 178.3). See also Chapter 179.

Abdominal Pain

Appendicitis

Appendicitis is the most common surgical emergency in pregnant patients. The incidence of appendicitis in pregnant patients is the same as that in nonpregnant patients, but delays in diagnosis contribute to an increased rate of perforation, which results in significant fetal mortality and maternal morbidity.47 There is also an increased rate of complications of appendicitis in pregnancy. A large, population-based study has found an almost twofold increase in sepsis and septic shock, transfusion, pneumonia, bowel obstruction, postoperative infection, and length of stay longer than 3 days.48 During the first half of pregnancy, diagnostic findings are usually similar to those in the nonpregnant woman, but the clinical picture becomes more atypical during the second half of pregnancy.

Traditionally, the appendix was thought to be displaced counterclockwise out of the right lower quadrant after the third month of gestation, with its ultimate location deep in the right upper quadrant, superior to the iliac crest (Fig. 178.8). However, one study has found that in only 23% of pregnant patients does the location change from the right lower quadrant, even in the third trimester. Displacement of the abdominal wall away from the abdominal viscera can result in difficulty in palpation of organs and loss of signs of parietal peritoneal irritation. The physiologic

Fig. 178.8. Locations of the appendix during succeeding months of pregnancy. In planning an operation, it is better to make the abdominal incision over the point of maximal tenderness unless there is great disparity between that point and the theoretic location of the appendix. PP, postpartum. (From Gabbe SG, Niebyl JR, Simpson JL, Galan HL: Obstetrics: normal and problem pregnancies, New York, 2007, Churchill Livingstone.)

increase in white blood cell count and erythrocyte sedimentation rate in pregnancy should also be considered in the evaluation of the patient with possible appendicitis because these may confuse the overall clinical picture.

Clinical Features. The gastrointestinal symptoms of appendicitis, such as anorexia, nausea, and vomiting, mimic those of pregnancy, particularly during the first trimester, making such symptoms relatively nonspecific. Right-sided abdominal pain is the most constant finding, although this is less reliable later in pregnancy. Peritoneal signs are also most common during the first trimester. The absence of fever, leukocytosis, or tachycardia has been reported. The lack of these clinical findings in pregnant patients with appendicitis may be the result of a blunted inflammatory response caused by elevated maternal levels of pregnancy-related steroids. Pyuria without bacteriuria is seen in up to 58% of patients.

Because of confounding factors, the misdiagnosis rate for appendicitis is 30% to 35% overall in pregnancy, with a 40% to 50% rate of removal of normal appendix during the third trimester. In contrast to the relative safety of performing an exploratory laparotomy or laparoscopy during pregnancy, the risk of fetal loss and maternal morbidity from failure to diagnose appendicitis and perforation is considerable, so clinical vigilance is required, even in the absence of classic signs. In later pregnancy, when peritoneal signs are often absent and the uterus obscures normal physical findings, diagnosis is frequently delayed, and the perforation rate may approach 25%.

Differential Diagnosis. Pyelonephritis, cholecystitis, nephrolithiasis, and pregnancy-related diseases such as ectopic pregnancy, broad ligament pain, corpus luteum cyst leakage, and ovarian torsion should be considered in the patient who has right-sided abdominal pain. Pyelonephritis is the most common condition that is confused with appendicitis. During its migration, the appendix is located very near the kidney, resulting in a high incidence of pyuria and flank pain (see Fig. 178.8). In cases of appendicitis, unless there is coincident urinary tract infection, the urine is free of bacteria, a feature distinguishing it from pyelonephritis. Salpingitis, another common misdiagnosis, is very rare in pregnancy, although it can occur before 12 weeks of gestation.

Diagnostic Testing. Leukocytosis is common in pregnant patients with appendicitis, although it is rarely high enough to distinguish it from the physiologic leukocytosis of pregnancy. Pyuria in a catheterized urine specimen suggests pyelonephritis,
PART V  Special Populations  |  SECTION TWO  The Pregnant Patient

**Gallbladder Disease**

Cholelithiasis is present in approximately 5% of pregnant women and is the second most common nonobstetric surgical condition in pregnant patients. The natural history of asymptomatic cholelithiasis is believed to be similar to that in nonpregnant women, with less than 50% of patients with gallstones developing symptoms.

Changes in gallbladder kinetics are believed to be due to high pregnancy-related steroid levels. Progesterone decreases smooth muscle tone and induces gallbladder hypomotility and cholestasis, causing an increased risk of stone formation. In addition, pregnancy induces changes in bile composition and increased cholesterol secretion, thus increasing the incidence of cholesterol stone formation.
Clinical Features

The signs and symptoms of acute cholecystitis during pregnancy are the same as those in nonpregnant women. Epigastric or right upper quadrant pain and tenderness and nausea predominate. Leukocytosis must be interpreted carefully because of the increased white blood cell count seen normally in pregnancy. Likewise, a slightly elevated amylase level can be normal during pregnancy, and alkaline phosphatase, which is produced by the placenta, may be twice the nonpregnant level. A history of self-limited pain episodes associated with food intake suggests the diagnosis.

Diagnostic Testing

Ultrasonography is a reliable means of recognizing stones in the gallbladder, although it may not differentiate symptomatic from asymptomatic stones. In the patient with right upper quadrant pain, simultaneous sonographic evaluation of the liver is useful but technically difficult, particularly during the third trimester, when subcapsular liver hematomas and other intrinsic hepatocellular disease can occur but the liver may be obscured under the ribs.

Differential Diagnosis

Pyelonephritis should be considered in the patient with right upper quadrant pain, with or without fever. During the third trimester, appendicitis can also be associated with right upper quadrant pain. Hepatitis and fatty liver infiltration occur in pregnancy; liver distention and inflammation associated with pregnancy-induced hypertension can also cause right upper quadrant pain. In addition, spontaneous intrahepatic bleeding can occur during late pregnancy, mimicking cholecystitis. Because of the potential for other serious diseases, diagnostic studies should be performed to verify a clinical diagnosis of symptomatic cholelithiasis and cholecystitis in pregnancy.

Management

The patient who has fever, leukocytosis, prolonged pain, or evidence of cholecystitis should be made NPO and given IV fluid hydration, adequate pain control, and broad-spectrum antibiotics. Some patients with uncomplicated cholecystitis can be managed medically. Patients with obstructive jaundice, gallstone pancreatitis, sepsis or failure to respond to conservative management are candidates for surgery (optimally, during the second trimester, if possible).

Discharge should be considered only for patients with uncomplicated and sonographically proven cholelithiasis who are not otherwise candidates for admission after consultation with an obstetrician. Pregnant patients with symptomatic cholelithiasis have a high rate of symptomatic relapse and increased severity of disease with each relapse. Early follow-up should be arranged, and the patient should be given careful instructions to return if she experiences fever, vomiting, or persistent pain. In one study, patients who were observed during pregnancy had a higher rate of pregnancy-related complications (36%) in contrast to much lower rates of complications in those who had a laparoscopic cholecystectomy.

Liver Disorders

Pregnancy is associated with several unique liver abnormalities in addition to more usual hepatic diseases. Emergency clinicians should recognize the various symptoms of liver disease during pregnancy, as well as the hepatic diseases unique to pregnant women. Liver metabolism increases during pregnancy, but hepatic blood flow is unchanged, and little change occurs in liver function. Bilirubin, transaminase, and lactate dehydrogenase levels and prothrombin times are unchanged from those in the nonpregnant state. Albumin levels decrease secondary to an increase in maternal circulating plasma volume. Alkaline phosphatase levels may be up to double the nonpregnant values, and amylase levels may also be slightly elevated.

Hepatitis

Hepatitis is the most common cause of liver disease in pregnancy, accounting for 40% of cases of jaundice in pregnancy. Management and treatment are supportive and unchanged from those for nonpregnant patients. Hepatitis E, however, has been reported to have a more aggressive course in pregnancy, with an increased maternal mortality rate and rate of fetal loss. Maintenance of adequate nutrition is a priority. Vertical transmission of hepatitis B can occur if the disease is not recognized. Pregnant women should be vaccinated. Prophylaxis should be administered to the newborn.

Acute Fatty Liver

Acute fatty liver of pregnancy is a disorder of the third trimester that can result in hepatic failure, complicated labor, and fetal mortality. The disease is rare, occurring most often in primiparous patients and patients with twin gestations.

The cause of acute fatty liver of pregnancy is unknown, although studies have suggested that a deficiency in the fetus’s fatty acid metabolism leads to an accumulation of hepatotoxic metabolites in the maternal circulation. On microscopic examination, fatty infiltration of the hepatocytes with edema and vacuolization can be seen, but there is no necrosis or inflammation. Liver function returns to normal after delivery if the patient can be supported through the acute phase. Although up to 50% of patients have signs of preeclampsia, the two are not clearly related. The diagnosis must be differentiated from viral hepatitis and HELLP syndrome, which have similar disease presentations and laboratory findings but, again, are not clearly related.

Clinical Features. Nausea and vomiting associated with malaise or jaundice during the third trimester should trigger consideration of a diagnosis of acute fatty liver. The right upper quadrant or epigastrium is usually tender. The disease may progress to coagulopathy, jaundice, seizures, DIC and hepatic encephalopathy. Hemorrhage from coagulopathy is the most common complication at delivery. The diagnosis is often delayed secondary to the multiple differential considerations.

Differential Testing. Typically, leukocytosis is present, the platelet count and fibrinogen level are low, prothrombin and partial thromboplastin times are elevated, and fibrin split products are present. In a series of 11 patients, increased transaminase and serum bilirubin concentrations were found in all patients, hypoglycemia was found in 18%, and hypoproteinemia was found in 46%55,66 In contrast to Reye’s syndrome, the serum ammonia level is only mildly elevated. Hyperuricemia is usually present. The bilirubin level is elevated late in the course of the disease. The CT scan and sonogram may be normal, so liver biopsy is used to make the definitive diagnosis.

Differential Diagnosis. Liver tenderness and coagulopathy usually suggest preeclampsia during the third trimester. Jaundice and increases in the ALT level are distinguishing features because they are unusual in cases of liver disease associated with pregnancy-induced hypertension. Similarly, rapid progression of hepatic failure, hypoglycemia, and coagulopathy is unlikely in cases of
The patient with viral hepatitis is likely to have more marked elevations in transaminase levels. Drug-induced hepatic failure should be excluded by history and toxicologic screening for acetaminophen or other toxins, if appropriate. Cholecystitis may be distinguished by ultrasound examination, but may also be characterized by right upper quadrant pain; it is not associated with coagulopathy or progressive liver failure.

**Management.** The patient with acute fatty liver of pregnancy may require acute stabilization for seizures or coma. Hypoglycemia may occur, which should be rapidly corrected with dextrose. Coagulation parameters should be assessed. Fluid resuscitation and replacement of clotting factors may be required, and the patient should be admitted to an obstetric service capable of managing this serious disease. The diagnosis is usually made with liver biopsy if the disease has not progressed to severe coagulopathy. Rapid delivery is usually advisable when the diagnosis has been established. Fresh-frozen plasma, platelet transfusions, and glucose may be needed to sustain the patient until delivery can be accomplished.

### Intrahepatic Cholestasis

Intrahepatic cholestasis of pregnancy, also termed *idiopathic jaundice of pregnancy*, *icterus gravidarum*, or *pruritus gravidarum*, is a rare syndrome that occurs during the third trimester of pregnancy. It is the second most common cause of jaundice in pregnancy, after hepatitis. On histologic examination, the disease is characterized by cholestasis and dilated canaliculi in the biliary tree. The liver is normal. It is more common with increasing maternal age, with multiple gestations, and in the winter months.

**Clinical Features.** Generalized pruritus and mild jaundice are the hallmarks of intrahepatic cholestasis of pregnancy. Only 20% of patients present with this combination, however, and 80% present with pruritus alone. The pruritus usually begins in the palms and soles and ascends to the trunk. Although insomnia and fatigue occasionally accompany the pruritus, the patient appears nontoxic, without fever, vomiting, diarrhea, or significant malaise. The bilirubin level is rarely above 5 mg/dL, the alkaline phosphatase level can be elevated sevenfold to tenfold, and transaminase levels are in the normal range. Resolution occurs when the woman delivers. Although maternal outcome is favorable, women with intrahepatic cholestasis of pregnancy are at increased risk for preterm delivery, meconium passage, and intrauterine fetal demise.

**Differential Diagnosis and Management.** Exclusion of more serious entities, such as viral hepatitis, acute fatty liver, drug-induced cholestasis, and complicated cholecystitis, is required. Outpatient management is appropriate, provided the diagnosis is clear and the patient has close obstetric follow-up. Some have advocated aggressive fetal surveillance and delivery after fetal lung maturity to improve the fetal outcome. Symptomatic treatment with antihistamines, ursoodeoxycholic acid, bile salts, gua gum, benzodiazepines, and other medications has been tried, with variable success.

### Nausea and Vomiting

**Normal Pregnancy**

Nausea and vomiting are common in pregnancy, particularly from 6 to 20 weeks of gestation. Symptoms are usually self-limited and often resolve with lifestyle changes, such as diet modification and avoidance of environmental triggers. Although evidence support-
to be therapeutic for intractable hyperemesis; however, it is considered a last-line agent and its risk profile should be weighed carefully before administration. In women who cannot maintain their weight despite medical therapy, enteral nutrition via a nasogastric (NG) tube should be considered.

**Thromboembolic Disease**

Thromboembolic disease accounts for almost 20% of obstetric mortality, making it the leading cause of death in pregnancy. Pregnancy is a hypercoagulable state, with increased coagulation factors and stasis as pregnancy progresses and significant vascular trauma at the time of delivery. The risk of venous thrombosis increases during pregnancy to five or six times that of nonpregnant women. Although the risk is increased throughout pregnancy, it is highest during the puerperium. Risk factors include smoking, obesity, age older than 35 years, hypercoagulable state, varicose veins, and prior superficial venous thrombosis. Women who deliver prematurely or have postpartum hemorrhage are also at higher risk.

**Clinical Features**

As in nonpregnant patients, clinical signs of pain, tenderness, and swelling are poor predictors of deep venous thrombosis (DVT) in pregnancy. The clinical diagnosis of pulmonary embolus (PE) is also difficult. Although tachypnea, tachycardia, dyspnea, and pleuritic pain are commonly associated with PE, the symptoms are nonspecific and may be associated with such diverse diseases as hepatic inflammation, pyelonephritis, and diaphragmatic impingement from a normal gravid uterus.

**Diagnostic Testing**

**Deep Venous Thrombosis.** Because of its widespread availability, Doppler ultrasonography is the first-line test for the diagnosis of DVT. An abnormal study result is usually sufficient reason to treat the pregnant patient. However, normal leg study results can be seen with isolated iliac vein disease, which is common in pregnancy and requires imaging with MRI or CT for diagnosis. If thromboembolic disease is suspected, serial indirect Doppler testing or CT may be required. The risk of anticoagulation usually outweighs the risk of definitive studies when the diagnosis is equivocal. Imaging with lung scintigraphy or CT angiography is recommended. Both have comparable performances for PE diagnosis during pregnancy, although CT angiography delivers a higher maternal radiation dose. Pulmonary angiography may be required if the diagnosis of PE is unclear after less invasive studies have been performed. Chest radiography (shoing the pelvis and uterus) should be performed to exclude other disease processes that may mimic a PE. The diaphragm is normally symmetrically elevated during late pregnancy.

**Management**

Warfarin (Coumadin) is contraindicated during pregnancy because of its teratogenic effects, high risk of abortions, and fetal hemorrhage. Heparinoids are used to treat thromboembolic disease during pregnancy. Unfractionated heparin carries a poorly understood risk of fetal osteoporosis, thrombocytopenia, prematurity, or miscarriage. In general, acute anticoagulation with IV heparin is followed by subcutaneous heparin bid, usually continued for 3 to 6 months postpartum in patients who have DVT or PE during pregnancy. Patients receiving this treatment require laboratory testing every 1 or 2 weeks, and the efficacy of anticoagulation may be variable during pregnancy.

Low-molecular-weight heparin is considered safe in pregnancy and offers several advantages over unfractionated heparin, including decreased bleeding risk, reliable pharmacokinetics, decreased risk of heparin-induced thrombocytopenia, fixed dosages, less frequent dosing, and decreased risk of osteoporosis and thrombocytopenia. In patients with a history of DVT or PE, prophylaxis for subsequent gestations is usually recommended.

**Genitourinary Infections**

**Urinary Tract Infection**

Asymptomatic bacteriuria in pregnancy predisposes the patient to the development of symptomatic lower and upper tract genitourinary infections. This has led to the US Preventive Services Task Force recommendation to screen for asymptomatic bacteriuria with urine culture in pregnant women at 12 to 16 weeks’ gestation or at the first prenatal visit, if later (grade A recommendation). Urinary pressure exerted on the bladder and ureters, poor emptying of the bladder with voiding, and progesterone-induced smooth muscle relaxation that inhibits ureteral peristalsis appear to contribute to an increased risk of infection during pregnancy. Prenatal screening of patients with asymptomatic bacteriuria in early pregnancy identifies approximately 95% of those at risk for subsequent bacteriuria during the pregnancy. Because up to 30% of women who have asymptomatic bacteriuria will have pyelonephritis if they are untreated, the treatment of bacteriuria is cost-effective and important.

**Clinical Features and Diagnostic Testing.** The pregnant patient who presents with lower urinary tract symptoms (eg, dysuria, frequency, urgency) or upper tract symptoms (eg, fever, malaise, back pain) should have a pelvic examination and evaluation of an uncontaminated urine specimen, preferably catheterized. There is a predominance of right-sided symptoms during pregnancy, probably the result of increased mechanical forces on the right ureter, but left-sided flank pain or bilateral symptoms may be caused by pyelonephritis. Rarely, urinalysis may yield normal results or cultures may produce negative findings because of failure to report lower colony counts or because of complete obstruction of the involved ureter.

The major risk of asymptomatic and lower urinary tract infection is spread to the renal parenchyma. Acute pyelonephritis carries considerable morbidity in pregnancy, including maternal sepsis, permanent renal injury, and premature labor. The risk of prematurity can be minimized by effective treatment and continued monitoring for recurrence. The development of premature labor in the woman who has pyelonephritis is ominous; it can be prevented only by aggressive recognition and treatment earlier in pregnancy.

**Differential Diagnosis.** Vaginitis, herpes genitalis, chlamydial infection of the urethra, and ovarian torsion can masquerade as urinary tract symptoms. A history of external dysuria (burning at the perineum with urination) suggests herpes or vaginitis. A pelvic examination should be performed to obtain cervical culture specimens and identify perineal or vaginal causes of dysuria. Appendicitis, cholecystitis, pancreatitis, and liver diseases in pregnancy must be considered in the differential diagnosis of an upper urinary tract infection. Back pain may also be a sign

A history of external dysuria (burning at the perineum with urination) suggests herpes or vaginitis. A pelvic examination should be performed to obtain cervical culture specimens and identify perineal or vaginal causes of dysuria. Appendicitis, cholecystitis, pancreatitis, and liver diseases in pregnancy must be considered in the differential diagnosis of an upper urinary tract infection. Back pain may also be a sign
Management. Patients with asymptomatic bacteriuria or lower urinary tract signs and symptoms should be treated with 7 to 10 days of an antibiotic that is active against usual urinary pathogens and safe in pregnancy. The most common choices are a cephalosporin, such as cephalexin, 500 mg orally qid for 3 to 7 days; nitrofurantoin, 100 mg orally bid for 3 to 7 days; or a sulfonamide, such as trimethoprim-sulfamethoxazole, 800/160 mg bid for 3 days (except during the third trimester). Emergency clinicians should consider factors such as cost, local availability, and side effects when selecting the best treatment option.77,78

Patients with fever, back pain, and evidence of acute pyelonephritis in pregnancy are usually admitted for IV antibiotic administration, although outpatient parenteral therapy can be effective and safe in selected patients.77 In such cases, aggressive IV hydration, obstetric consultation, and testing of urine cultures should be initiated. At least one parenteral dose of antibiotics should be given, with antibiotic coverage guided by known organism susceptibilities in a given hospital. Because the resistance of Escherichia coli to ampicillin is considerable in most regions, a cephalosporin, such as ceftriaxone, 1 g IV bid, is usually administered. Culture testing must be performed to ensure that the original choice of antibiotic was correct, and the patient must have a repeated culture and be observed closely after treatment.

Vaginitis

Bacterial Vaginosis. Bacterial vaginosis (formally known as Gardnerella vaginitis or Haemophilus vaginalis vaginitis) is an overgrowth of multiple endogenous vaginal bacteria, in some cases producing excessive discharge and vaginal malodor. Prevalence rates for bacterial vaginosis in pregnancy are estimated at 15% to 20%. Bacterial vaginosis is associated with an increased risk of chorioamnionitis, subclinical PID, premature rupture of membranes, fetal prematurity, and postpartum endometritis after vaginal delivery. However, treatment of bacterial vaginosis is directed toward symptomatic relief for the patient and does not necessarily improve fetal outcomes. Management includes a 7-day course of metronidazole or 7-day course of clindamycin. Intravaginal treatment is not recommended in pregnant patients.77,78

Candida albicans Vaginitis. The incidence of vulvovaginal candidiasis is increased during pregnancy by high levels of estrogen and other steroids. Oral azoles are contraindicated in pregnancy because of an association with adverse fetal outcomes. Treatment with vaginal azoles for 7 days during pregnancy is considered safe, with an estimated 85% to 100% cure rate.77,78 Recurrent disease may require a vaginal culture to confirm diagnosis and identify unusual candidal species (eg, Candida glabrata) that may be resistant to conventional treatment. Longer treatment or treatment of a potential Candida reservoir in the patient’s sexual partner(s) may also be required. However, there is no association of Candida colonization with adverse pregnancy outcomes, and treatment is for relief of symptoms only.77,78

Trichomonas Vaginitis. Trichomoniasis is a sexually transmitted vaginitis caused by a protozoan parasite, Trichomonas vaginalis. Of patients who have trichomoniasis, 50% are asymptomatic. Symptoms include vaginal itching, malodorous discharge, and vaginal irritation. Diagnosis is made by direct visualization or protozoans on wet mount. The recommended treatment is metronidazole, a one-time dose of 2 g, for symptomatic patients only.77 Although trichomoniasis has been associated with increased prematurity, treatment with metronidazole has not been shown to improve fetal outcomes, so emergency clinicians should counsel patients and consider deferment of treatment in asymptomatic pregnant women until after 37 weeks’ gestation.

Sexually Transmitted Disease

Sexually transmitted diseases are treated in pregnant patients according to the latest CDC guidelines. In general, the tetracyclines and quinolones are contraindicated in pregnant patients. Treatment of genital tract infections may be important in preventing preterm labor and decreasing transmission to the infant.

Chlamydia trachomatis. Chlamydia trachomatis infection is the most common sexually transmitted disease in the United States and worldwide. Its prevalence is currently three to five times that of Neisseria gonorrhoeae infection. Clinical diagnosis is difficult during pregnancy because cervical mucus is usually cloudy and contains white blood cells, but urine sampling can be done and is equivalent to endocervical sampling in pregnancy infections.79 Routine chlamydial screening during pregnancy is important to prevent complications of preterm labor and postpartum endometritis, both of which are more common in patients who have chlamydial cervical infections. Chlamydial infections of infants born to infected mothers include conjunctivitis and pneumonia. Treatment during pregnancy or breast-feeding is azithromycin (single 1-g dose), which improves compliance and decreases gastrointestinal side effects; a 7-day course of amoxicillin is an acceptable alternative.78

Herpes Simplex. Herpes simplex virus infections pose a significant risk in pregnancy to the mother and newborn. Women who have genital herpes during the third trimester have a 30% to 50% increased risk of transmission compared with women with herpes simplex virus infection in the first trimester (1%). The virus can be transmitted prenatally through placental infection or ascending vaginal infection and by vaginal delivery, particularly when herpetic lesions are present. Infections in the neonate often are disseminated or involve the CNS, causing significant morbidity and mortality. In the ED, culture of new suspected herpetic lesions of the cervix, vagina, or perineum identifies patients at risk for perinatal complications. Although the risk of oral acyclovir and valacyclovir use in pregnancy is not well known, it is recommended for first-episode genital herpes. Suppressive therapy can reduce the need for cesarean section in women whose first clinical episode of genital herpes simplex occurred during pregnancy but may not eliminate the need for cesarean section in women with recurrent herpes simplex. Treatment should be undertaken with obstetric consultation and careful patient monitoring.

Neisseria gonorrhoeae. Gonococcal infection of the cervix occurs during pregnancy in 1% of women. Symptoms are similar to those in nonpregnant women. Salpingitis is rare but may develop during the first trimester from upper genital extension of cervical infection. Some practitioners believe that the incidence of the disseminated infection is increased in pregnant women because of elevated progesterone levels and increased vascularity in the area of the cervix. Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy; treatment includes cephalosporins or azithromycin.77 Treatment of possible coexistent chlamydial infection is recommended for pregnant and nonpregnant women. The major complications of third-trimester gonococcal infection are neonatal gonococcal ophthalmia and sepsis.78,80
Upper Genital Tract Infection

Pelvic Inflammatory Disease. PID is very rare in pregnancy and does not occur after the first trimester. The differential diagnosis includes ectopic pregnancy, septic abortion, and appendicitis, all of which are more common. In the patient with suspected infection, smears or cultures for Chlamydia and gonorrhea should be performed. Given the risk of endometrial infection in pregnancy and the need to consider other diagnoses, pregnant patients who have suspected PID require hospitalization and IV antibiotics.\(^7\)

Chorioamnionitis. Chorioamnionitis is the infection or inflammation of the placenta and fetal membranes. After 16 weeks of pregnancy, the chorioamniotic membranes adhere to the cervix and may become infected. The risk is increased in women with preterm labor. Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness in a patient past 16 weeks of pregnancy.\(^5\) Leukocytosis can be suggestive of chorioamnionitis but is not diagnostic. Patients should have blood specimens drawn for culture. Vaginal and cervical culture specimens for group B streptococci, E. coli, chlamydia, and gonorrhea should also be obtained. Urgent obstetric consultation should be obtained, and hospitalization for IV administration of antibiotics is required. Patients are usually treated with IV ampicillin and gentamicin. In addition, a study has reported that antenatal steroids may reduce adverse neonatal outcome after a preterm birth associated with chorioamnionitis.\(^8\)

Thyroid Disorders

Thyroid disorders are common in women of childbearing age. During pregnancy, however, this is associated with a range of adverse maternal and fetal outcomes, including spontaneous miscarriage, preeclampsia, heart failure, preterm delivery, intrauterine growth restriction, and stillbirth.\(^5,35\) The evaluation and management of pregnant women with thyroid dysfunction parallel those of nonpregnant women, but require attention to the physiologic changes to the thyroid gland that occur during pregnancy.

Normal pregnancy exerts a significant amount of stress on the thyroid gland. During pregnancy, the thyroid gland increases in size, requires more iodine, and produces more thyroid hormone than in the nonpregnant state. Moreover, maternal and fetal thyroid function are strongly linked, with maternal thyroxine accounting for a substantial portion of fetal thyroid function at birth.\(^8\) Thyroid dysfunction in pregnancy can occur during pregnancy or the postpartum state.

Hyperthyroidism, characterized by suppressed TSH levels, elevated T\(_4\) and/or T\(_3\), occurs in only 0.1 to 0.4% of all pregnancies.\(^8\) Hyperthyroidism in pregnancy can be a result of any cause, but Graves’ disease and hCG-mediated hyperthyroidism are the most common causes. Graves’ disease is an autoimmune process associated with thyroid-stimulating antibodies and usually becomes less severe during the later stages of pregnancy.\(^33\) hCG, which is homologous to thyroid-stimulating hormone (TSH), has some thyroid-stimulating activity and may transiently cause hyperthyroidism in the first half of gestation. hCG-mediated hyperthyroidism is typically less severe than Graves’ disease-associated hyperthyroidism.

Hypothyroidism complicates 2% to 3% of pregnancies. Although nutritional iodine deficiency is a common cause of hypothyroidism globally, it is rare in the United States. When US women are diagnosed with hypothyroidism, the most common cause is Hashimoto’s (autoimmune) thyroiditis, in which autoantibodies cause destruction of the thyroid gland. Hypothyroidism is associated with adverse pregnancy effects, including preeclampsia, placental abruption, low birth weight, and an increased risk of stillbirth.

Postpartum thyroiditis is characterized by transient hyperthyroidism and/or hypothyroidism in the postpartum period. It is estimated that 5% to 10% of women have postpartum thyroiditis. Most women return to a euthyroid state within 1 year postpartum, but approximately 25% of these women develop permanent hypothyroidism in the subsequent 10 years. The diagnostic triad consists of the lack of previous history of thyroid disorder, an abnormal TSH concentration during the first postpartum year, and the absence of TSH receptor antibodies (Graves’ disease) or a toxic nodule.

Clinical Features

The diagnosis of thyroid dysfunction during pregnancy is difficult because pregnancy itself can mimic the findings in mild to moderate hypothyroidism and hyperthyroidism.

Hyperthyroidism in pregnancy should be suspected when the patient exhibits disproportionate tachycardia, thymoegaly, exophthalmos, weight loss, or inadequate weight gain during pregnancy. Hyperthyroidism may be associated with a hydatidiform mole and usually resolves with evacuation of the mole. Patients may present with signs of thyroid storm, including altered mental status, severe tachycardia, and signs of high-output heart failure (eg, edema, dyspnea, orthopnea).

Like hyperthyroidism, hypothyroidism in pregnancy is difficult to diagnose. Signs such as edema, fatigue, and/or weight gain may be attributed to the pregnancy rather than thyroid dysfunction. Enlargement of the thyroid gland may be absent depending on the cause of the hypothyroidism. The diagnosis of hypothyroidism during pregnancy should be suspected when the patient exhibits edema, dry skin, hair loss, and a prolonged relaxation phase of deep tendon reflexes.

Patients with postpartum thyroiditis classically present with thyrotoxicosis 6 weeks to 6 months postpartum, followed by a hypothyroid state lasting up to 6 months. A euthyroid state returns by the end of the first postpartum year. However, most patients present with hyperthyroidism alone or lone hypothyroidism. The recurrence rate in subsequent pregnancy is estimated at 69%, and 25% of women eventually develop permanent hypothyroidism.

Diagnostic Testing

Normal values of thyroid hormones vary based on stage of pregnancy. The diagnosis of hyperthyroidism is confirmed by a low (<0.1 mU/L) or undetectable (<0.01 mU/L) serum TSH level and levels of free triiodothyronine (T\(_3\)) and thyroxine (T\(_4\)) that exceed the normal range for pregnancy. Confirmation of hypothyroidism is based on an elevated serum TSH level, relying on trimester-specific TSH reference ranges.\(^8\) Overt hypothyroidism is defined as an elevated trimester-specific TSH, along with a decreased, trimester-specific free T\(_4\) concentration. Subclinical hypothyroidism is defined as an elevated trimester-specific serum TSH concentration and a normal free T\(_4\) concentration.

Differential Diagnosis

Thyroid dysfunction should be considered in the patient with nonspecific symptoms, including fatigue, anxiety, depression, and unexplained weight loss or weight gain. When a diagnosis of hypothyroidism or hyperthyroidism is recognized, their respective causes and differential diagnoses should be considered (see Chapter 120 for more detailed information).
Management

No treatment is usually required for hCG-mediated hyperthyroidism. Treatment of pregnant women with overt hyperthyroidism due to Graves’ disease is of utmost importance because good fetal and maternal outcomes depend on controlling the mother’s hyperthyroidism. Although thyroid ablation with radioactive iodine is contraindicated in pregnancy, medical treatments are available. Propylthiouracil (PTU) is the preferred treatment of hyperthyroidism in the United States. Methimazole is equally effective at treating hyperthyroidism in pregnancy but may be associated with fetal anomalies such as aplasia cutis, esophageal atresia, and choanal atresia. It is therefore not recommended as first-line treatment for hyperthyroidism in pregnancy.

Patients with symptoms of thyroid storm should be managed in an intensive care setting. Treatment with PTU should be initiated early. Dexamethasone is recommended to block the peripheral conversion of T₄ to T₃. Beta blockers should be considered to control tachycardia; labetalol, esmolol, and propranolol have been used intrapartum. A subtotal thyroidectomy may be effective at treating hyperthyroidism in pregnancy but may be associated with fetal anomalies such as aplasia cutis, esophageal atresia, and choanal atresia. It is therefore not recommended as first-line treatment for hyperthyroidism in pregnancy.

Hypothyroidism in pregnancy is managed with levothyroxine supplementation (2 µg/kg/day). Patients in the hypothyroid phase of postpartum thyroiditis require levothyroxine when they have a TSH level higher than 10 mU/L or between 4 and 10 mU/L with symptoms or active pregnancy attempt. The hyperthyroid phase of postpartum thyroiditis is usually managed with limited course of beta blockers.

Disorders of the Hypothalamic-Pituitary Axis

The pituitary is normally enlarged in pregnancy due to estrogen stimulation. Disorders of the hypothalamic-pituitary axis may increase the incidence of maternal and fetal morbidity and mortality.

Pregnancy profoundly affects the hypothalamic-pituitary axis, resulting in increased circulating levels of cortisol and adrenocorticotropic hormone due to increased estrogen production. In contrast, levels of growth hormone decrease in pregnancy. Disorders of the hypothalamic-pituitary axis in pregnancy can result in adrenal insufficiency, Cushing’s syndrome, acromegaly, diabetes insipidus, and prolactinomas. Although these disorders are rare, they are associated with maternal morbidity (eg, hypertension, hyperglycemia, eclampsia) and up to 20% fetal mortality.

Clinical Features

Disorders of the hypothalamic-pituitary axis usually present as an insidious set of chronic symptoms, many of which can mimic normal pregnancy, making diagnosis difficult. Symptoms vary depending on the specific disease but include fatigue, malaise, vomiting, weight gain or loss, amenorrhea, galactorrhea, and hyperprolactinemia. Normal pregnancy can be associated with slight decreases in the serum sodium level; more severe decreases in the serum sodium level may be signs of diabetes insipidus or adrenal insufficiency.

Diabetes insipidus may also be caused by pituitary infarction in the setting of severe obstetric hemorrhage (Sheehan’s syndrome). Advancements in the management and resuscitation of obstetric hemorrhage have made Sheehan’s syndrome increasingly rare, but it remains an important clinical consideration. The symptoms of Sheehan’s syndrome are dependent on the degree of the patient’s hypopituitarism. Patients present with signs and symptoms that vary, according to the deficient hormones. The failure of postpartum lactation and resumption of normal menstruation are strongly suggestive of Sheehan’s syndrome. Following postpartum hemorrhage, patients may have persistent tachycardia, hypotension, and latency between hemorrhage, and the onset of symptoms can vary, from months to years after pregnancy.

Diagnostic Testing

Diagnostic considerations vary according to the patient’s presentation. Growth hormone levels are elevated in patients with acromegaly. Patients with adrenal insufficiency may present with hyponatremia and hyperkalemia, although these may be absent in many patients. MRI is helpful in the detection of prolactinoma or Sheehan’s syndrome.

Differential Diagnosis and Management

Stabilization consists of treatment of serious manifestations, such as hyperkalemia, tachycardia, and hypotension. Outpatient management is appropriate in the stable patient, provided there is urgent endocrinology follow-up.

ACKNOWLEDGMENT

We thank Dr. Debra Houry and Dr. Jean Abbott for their contributions to previous editions of this chapter.
Hyperemesis gravidarum is defined as nausea and vomiting that begin during the first trimester of pregnancy and persist for more than 12 weeks. It is a severe form of nausea and vomiting in pregnancy and can lead to significant dehydration, electrolyte imbalances, and weight loss. Treatment typically involves administration of oral hydration, antiemetics such as vitamin B6, and occasionally intravenous fluid rehydration.

Acute fatty liver of pregnancy is a rare disorder of the third trimester characterized by fatty liver, high levels of liver enzymes, and coagulopathy. It is associated with high mortality and can be fatal if left untreated. Treatment includes intensive monitoring, hydration, and possibly early delivery.

Hepatitis is the most common cause of liver disease in pregnancy; it is usually viral in origin. During pregnancy, albumin levels decrease while alkaline phosphatase levels may increase up to double; amylase levels may also be slightly elevated.

Cholelithiasis presents with similar symptoms to those in nonpregnant women and is similarly diagnosed through ultrasound, CT, and MRI. It can also be diagnosed by ultrasound during pregnancy.

Appendicitis is the most common surgical emergency in pregnancy. Clinical presentations may be atypical, leading to a misdiagnosis rate of 30% to 35% in pregnant patients. Right lower quadrant pain is the most common finding, especially early in pregnancy. Ultrasound, CT, and MRI are useful for the diagnosis.

Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness. Treatment includes antibiotics such as ampicillin and gentamicin.

Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy; treatment includes ceftriaxone and doxycycline.

Thyroid Disease

During pregnancy, the thyroid gland increases in size, requires more iodine, and produces more thyroid hormone than in the nonpregnant state.

Hyperthyroidism, characterized by suppressed TSH levels and elevated T3 and/or T4, occurs in only 0.1% to 0.4% of all pregnancies. Graves’ disease and hCG-mediated hyperthyroidism are the most common causes.

When US women are diagnosed with hypothyroidism, the most common cause is Hashimoto’s (autoimmune) thyroiditis.

Postpartum thyroiditis is characterized by transient hyperthyroidism and/or hypothyroidism in the postpartum period. Approximately 25%
of these women develop permanent hypothyroidism in the subsequent 10 years.

- Hyperthyroidism may be associated with a hydatidiform mole and usually resolves with evacuation of the mole.
- The diagnosis of hyperthyroidism is confirmed by a low (<0.1 mU/L) or undetectable (<0.01 mU/L) serum TSH level and levels of free T3 and T4 that exceed the normal range for pregnancy.
- Confirmation of hypothyroidism is based on an elevated serum TSH level, relying on trimester-specific TSH reference ranges.

- Propylthiouracil (PTU) is the preferred treatment of hyperthyroidism in the United States. For thyroid storm, dexamethasone and beta blockers are added, with the patient under observation in the intensive care unit.
- Hypothyroidism in pregnancy is managed with levothyroxine supplementation (2 µg/kg/day).

REFERENCES

178.1. An 18-year-old G1P0 at 8 weeks of gestation presents with abdominal pain and vaginal bleeding for 1 day. Her serum human chorionic gonadotropin (hCG) level is 3,700 IU/L. Transvaginal ultrasonography does not reveal an intrauterine pregnancy (IUP) or mass. The pelvic examination is remarkable for a closed cervical os and a small amount of blood. Which of the following should be the next step?

A. Coagulation panel
B. Gynecologic consultation
C. RhoGAM, 300 µg intramuscularly
D. Repeat hCG in 2 days
E. Serum progesterone level

**Answer:** A. Ultrasonographic detection of an IUP is likely at hCG levels higher than 1500 to 2000 IU/L. A negative ultrasound, with an hCG level of 3700 IU/L, is concerning for an ectopic pregnancy or miscarriage. β-hCG levels should peak at the 7- to 10-week range, with mean values of 50,000 IU/L. A persistently low hCG level is even more suspicious for ectopic pregnancy, and gynecologic consultation is warranted.

178.2. A 36-year-old G3P2 presents with painless vaginal bleeding during the past hour. She is at 33 weeks of gestation, and her pregnancy has been uncomplicated. Her bleeding lasted approximately 20 minutes. Appropriate management includes all of the following except which one?

A. Baseline hemoglobin level and platelet count
B. Immediate complete pelvic examination
C. Immediate obstetric consultation
D. Intravenous fluid resuscitation
E. Transvaginal ultrasound

**Answer:** B. Painless late pregnancy bleeding is placenta previa until proven otherwise. Digital or instrumental probing of the cervix should be avoided until the diagnosis is excluded via ultrasonound. An injudicious vaginal examination can precipitate severe hemorrhage in the patient with an asymptomatic or minimally symptomatic placenta previa.

178.3. In pregnancy, treatment is indicated in each of the following sexually transmitted diseases except which one?

A. *Chlamydia trachomatis*
B. Herpes simplex virus
C. *Neisseria gonorrhoeae*
D. Pelvic inflammatory disease (PID)
E. *Trichomonas vaginalis*

**Answer:** B. Appendicitis is the most common surgical emergency in pregnancy. Clinical presentations may be atypical, particularly during the second half of pregnancy.
178.7. For the treatment of nausea and vomiting in pregnancy, which of the following has been found to have some associated risk of fetal abnormalities?

A. Diclegis (delayed-release combination of doxylamine and pyridoxine)
B. Ginger
C. Metoclopramide
D. Ondansetron
E. Promethazine

**Answer:** D. Ondansetron has been shown in studies to be linked with fetal cardiac abnormalities, as well as cleft lip and palate. Diclegis is first-line pharmacologic treatment of nausea and vomiting in pregnancy; metoclopramide and promethazine are alternatives if it fails. Ginger, a nonpharmacologic treatment, has been shown to be safe and effective at a dose of 250 mg qid.

178.8. Which of the following is not considered a normal physiologic change in pregnancy?

A. Decreased albumin level
B. Increased D-dimer level
C. Increased serum amylase level
D. Increased serum bilirubin level
E. Increased WBC count

**Answer:** D. Bilirubin, transaminase, and lactate dehydrogenase levels and prothrombin times are unchanged from the nonpregnant state. Albumin levels decrease secondary to an increase in maternal circulating plasma volume. Alkaline phosphatase levels may be up to double the nonpregnant values, and amylase levels may also be slightly elevated. The D-dimer level can be substantially elevated, even in normal pregnancy.
**PRINCIPLES**

The physiologic changes that occur in pregnancy may exceed the patient’s underlying compensatory mechanisms, resulting in initial symptom onset or rapid decompensation of medical illness during pregnancy. Certain chronic medical conditions also pose a serious threat to the mother’s health or result in a poor fetal outcome. Finally, some medical illnesses result in a difficult delivery or the need for special resuscitation measures in the neonate.

The incidence of pregnancy in chronically ill patients has been increasing because of improved survival of patients with diseases such as diabetes, epilepsy, renal failure, obesity, and various cancers. Also, the demographics of pregnancy are changing in that maternal age at the time of first pregnancy is increasing. Advances in assisted reproduction, including in vitro fertilization and oocyte donation, have made it possible for older women—including those who are postmenopausal—to become pregnant. Older pregnant women experience an increased rate of antepartum and intrapartum complications and are more likely to have comorbid conditions such as cardiovascular disease.

The recognition of an unexpected or even expected pregnancy may occur in the setting of the emergency department (ED), and many interventions are time-sensitive, mandating treatment in the ED. All emergency clinicians should have an understanding of critical diagnostic and treatment possibilities when encountering a pregnant patient with a preexisting illness.

**ASTHMA**

Asthma is one of the most common chronic medical problems in pregnancy, with a prevalence of between 3.7% and 9.4%. Maternal asthma is associated with an increased risk of preeclampsia or eclampsia, premature contractions, cesarean section, low birth weight, and small-for-gestational-age status. The risk of such complications varies with the severity of the disease and degree of control during pregnancy. Adverse perinatal outcomes increase with the severity of asthma during pregnancy. Controlling asthma during pregnancy leads to less intrauterine growth retardation and fewer adverse perinatal outcomes. It has been well documented that asthma may worsen, improve, or remain the same during pregnancy, but no studies have examined whether this is caused by changes in asthma treatment, severity, or sudden asthma attacks.

Maternal respiratory function changes can make it more difficult to recognize the decompensating pregnant asthmatic patient. Tidal volume and minute ventilation increase by 45% over the course of pregnancy resulting in an average PCO₂ of 32 mm Hg. The kidneys compensate and maintain an average bicarbonate level of 19 mEq/mL, which results in a compensated respiratory alkalosis with a serum pH between 7.40 and 7.45.

Many adverse perinatal outcomes caused by asthma are thought to be due to fetal hypoxia. Thus, the overall goal of treatment is maintaining maternal oxygen saturations above 95%. Both the American College of Obstetrics and Gynecology (ACOG) and National Asthma Education and Prevention Program have clearly stated that it is safer to use asthma medications to treat pregnant women than to allow severe asthma symptoms and exacerbations to occur during pregnancy.

The standard treatment for a pregnant asthmatic patient is the same as that for a nonpregnant patient with an asthma exacerbation. After history and the performance of a physical examination, the peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV₁) should be measured. Patients with an FEV₁ or PEF less than 50% of their predicted maximum are classified as having a severe exacerbation. An initial fetal assessment should be performed, including fetal heart tones and continuous electronic fetal monitoring with a biophysical profile if the pregnancy has reached viability. Supplemental oxygen should be given to all mothers with oxygen saturation below 95%.

Inhaled short acting β₂-agonists are the first-line treatment for an asthma exacerbation and can be given continuously, if needed, for a severe exacerbation (Table 179.1). Long-acting selective β₂-agonists and inhaled corticosteroids, with budesonide being the preferred agent, can be added as controller medications on discharge from the ED. Multiple studies have shown no increased risk of adverse perinatal outcomes. Nonselective β-agonists such as epinephrine are generally avoided because of concern for their effect on placental blood flow. It is important to note that β-agonists are tocolytics and will often halt labor.

Oral corticosteroids are indicated for use in moderate to severe asthma exacerbations and should be prescribed for the same indications as in nonpregnant asthmatics. Despite these recommendations, in multiple studies in the acute care setting, pregnant women with asthma exacerbations were between 17% and 21% less likely to be treated with oral corticosteroids than nonpregnant controls. Reasons for this treatment disparity may be due to evidence that oral corticosteroid use increases the risk of preterm delivery and low-birth-weight infants; there is also conflicting evidence of an increased risk of orofacial clefts. However, the benefits of oral corticosteroid use for avoiding fetal hypoxia outweighs the risk of adverse perinatal outcomes.

Second-line agents for asthma control (eg, cromolyn sodium) are considered safe in pregnancy. In limited studies, magnesium has been shown to improve respiratory function in pregnant females with severe asthma exacerbations without adverse fetal outcomes.

**CARDIOVASCULAR DISORDERS**

**Principles**

Heart disease complicates more than 1% of pregnancies in the United States and leads to 20% of nonobstetric maternal deaths. Hypertensive disorders are the most frequent cardiovascular events, occurring in 6% to 8% of pregnancies. The

A hypertensive emergency as acute-onset persistent hypertension with systolic blood pressure greater than 160 mm Hg or diastolic blood pressure greater than 110 mm Hg. In these cases, parenteral therapy is indicated, with a target blood pressure range of 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic, to prevent loss of cerebral autoregulation. Therapy with intravenous (IV) labetalol is preferred, although hydralazine and oral nifedipine are also considered first-line treatment (Table 179.4). Although labetalol is recommended by the ACOG, it should be noted that regular beta blocker use during the first trimester has been associated with small-for-gestational-age newborns.

In 2013, the ACOG changed its diagnostic criteria for preeclampsia to no longer requiring proteinuria. In the absence of proteinuria, preeclampsia is diagnosed as hypertension in the presence of thrombocytopenia, impaired liver function, pulmonary edema, visual disturbances, and/or the development of renal insufficiency.

### Cardiac Disorders

#### Acute Coronary Syndromes

Pregnancy-related acute myocardial infarction (AMI) occurs in 6.2 of every 100,000 deliveries. The mortality rate in pregnant women who have had an AMI is from 5.1% to 7.2%. Pregnant women are two to four times more likely to have an AMI as compared to age-matched nonpregnant individuals. As the number of women becoming pregnant who are older than 35 years increases, it is important to recognize that pregnant women aged 40 years or older have a 30-fold greater risk for acute coronary syndrome (ACS) than pregnant women 20 years of age or younger. The incidence of AMI is highest during the last trimester and peripartum period.

Multiple factors are hypothesized to increase the risk of AMI in pregnancy, including a prothrombotic state, increased myocardial oxygen demand secondary to increased cardiac output and heart rate, and decreased oxygen-carrying capacity secondary to...

<td>Asthma</td>
<td>Fetal—IUGR, PTD, hypoxia, meconium-stained amniotic fluid, fetal loss Maternal—preeclampsia, gestational hypertension, gestational diabetes, hyperemesis gravidarum, need for labor induction</td>
<td>Good prenatal outcomes seen in well-controlled asthma Treatment of acute exacerbations is the same as for the nonpregnant patient with the goal of keeping maternal oxygen saturations &gt;95% to prevent fetal hypoxia. Fetal monitoring is recommended for exacerbations during the third trimester, even in the absence of maternal hypoxia. Maintenance therapy also is unchanged, with the following precautions: • Corticosteroids—inhaled agents preferred, but oral route may be necessary with acute exacerbations or severe, persistent disease; patients receiving long-term steroids require “stress dose” hydrocortisone during labor and delivery. • Methylxanthines—safe but debatable benefit; use only in refractory disease; reduced clearance during pregnancy may result in maternal toxicity and fetal tachycardia. • Leukotriene receptor antagonists—avoid zileuton.</td>
</tr>
<tr>
<td>Acute coronary syndrome</td>
<td>Fetal—perinatal death, PTD Maternal—uterine hemorrhage, abruptio placentae (related to use of antiplatelet, antithrombotic, fibrinolytic agents)</td>
<td>Standard medical therapy is the same as for the nonpregnant patient, although antiplatelet, antithrombotic, and fibrinolytic agents are best avoided when delivery is imminent. Avoid maternal hypotension when nitrates are used; they may result in fetal distress. Avoid beta blockers in the first trimester because they may cause fetal growth restriction. Coordinate definitive care (fibrinolytics vs. percutaneous coronary intervention) with cardiologist.</td>
</tr>

Special Populations

SECTION TWO

The Pregnant Patient

### Valvular heart disease

- **Fetal—** perinatal death, PTD
- **Maternal—** heart failure, thromboembolism, death

Appropriate antithrombotic therapy is indicated for patients with prosthetic valves and atrial fibrillation (see text).

**Mitral stenosis**—diuresis and beta blockade; avoid volume depletion when diuretics are used; valvuloplasty or open cardiac surgery for severe symptomatic disease; consider early pregnancy termination in women with severe stenosis.

**Mitrail and aortic regurgitation**—diuresis in patients with pulmonary congestion; surgical therapy for acute regurgitant lesions.

**Aortic stenosis**—avoid hypotension and supine hypotensive syndrome; vigorous fluid replacement during delivery; valvuloplasty or open cardiac surgery for severe symptomatic disease; consider early pregnancy termination with severe symptoms despite therapy.

### Hypertension

- **Fetal—** perinatal death, IUGR, PTD
- **Maternal—** progression of target end-organ damage, superimposed preeclampsia, abruption, cardiac decompensation

Most perinatal complications occur in patients with preeclampsia or secondary causes of hypertension; outcomes are usually good with mild essential hypertension, and ACOG does not recommend treatment for blood pressures $<160$ mm Hg systolic or $<10$ mm Hg diastolic.

The major risk posed by chronic hypertension in pregnancy is progression to preeclampsia, which occurs in 25% of these pregnancies.

The most commonly used agents include methyldopa (preferred agent), labetalol, and hydralazine.

Avoid beta blockers in the first trimester because they may cause fetal growth restriction and may also decrease placental blood flow.

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers are teratogenic.

Fetal cyanide poisoning might develop after several hours of sodium nitroprusside. Avoid prolonged infusions; use as agent of last resort.

### Iron deficiency anemia

- **Fetal—** low birth weight, PTD, low fetal iron stores, fetal loss (with severe anemia)
- **Maternal—** preeclampsia, high-output heart failure (rare); effects on maternal mortality unclear

Oral iron supplementation is indicated for patients with iron deficiency anemia. Recent evidence also supports prophylactic iron supplementation in pregnant patients. Several over-the-counter preparations are available.

There is a delay from onset of therapy to an increase in the serum hemoglobin level.

Parenteral iron replacement is safe and effective, although rarely required.

Transfusion is rarely required but is a consideration for fetal well-being in mothers with severe anemia.

### Sickle cell anemia

- **Fetal—** fetal loss, IUGR, PTD, premature rupture of membranes
- **Maternal—** need for cesarean section, preeclampsia, infection, heart failure, pulmonary infarction, incidence of painful crises; maternal mortality low with treatment; false-positive Apt and Kleihauer-Betke test results secondary to persistent hemoglobin F

Management of pain crises and infections is the same as for the nonpregnant patient, with rest, hydration, narcotic analgesia, supplemental oxygen, and antibiotics, as indicated.

Narcotic analgesics should not be withheld, but the need for neonatal respiratory support should be anticipated if delivery is imminent.

Prophylactic transfusion is not indicated.

Fetal monitoring and assessment of fetal well-being are indicated for viable pregnancies.

Chronic maintenance care includes pneumococcal vaccination and supplemental folate. Hydroxyurea has been discouraged during pregnancy, but few adverse fetal effects have been reported in humans.

### Epilepsy

- **Fetal—** various congenital malformations associated with AEMs, fetal hypoxia and bradycardia, fetal loss
- **Maternal—** variable changes in seizure frequency; alterations in AEM levels; increased seizure frequency secondary to voluntary medication noncompliance; abortion, anemia, hyperemesis gravidarum, preeclampsia, possible need for labor induction and cesarean section, premature rupture of membranes

Management of status epilepticus is the same as for the nonpregnant patient. Maintenance therapy should be coordinated by the patient’s neurologist (or primary care practitioner) and obstetrician. In general, a single AEM given at the lowest effective dose is recommended.

The newer AEM levetiracetam has demonstrated a lower incidence of birth defects and has equal to better efficacy as older AEMs.

Folate supplementation (at least 0.4 mg/day) is indicated for patients taking AEMs.

Consider administration of oral vitamin K to the mother during the last month of pregnancy and parenteral vitamin K to the newborn.

| HIV/AIDS           | Fetal—HIV infection, PTD, low birth weight, fetal loss, neonatal abstinence syndrome if mother uses injection drugs, teratogenicity associated with efavirenz (EFV) use Maternal—postpartum endometritis, uterine bleeding (in the setting of thrombocytopenia), progression of HIV disease in absence of HAART therapy | Antiretroviral therapy—  
  - Highly active antiretroviral therapy (HAART) should be offered to all pregnant patients with HIV infection and viral load >1000 copies/mL. The HAART regimen should include zidovudine (AZT) to prevent vertical transmission of the virus.  
  - There are specific HAART drug-related concerns during pregnancy; decisions about therapy are best made by appropriate specialists.  
  - AZT monotherapy is not recommended except for those patients with a low viral load who do not wish to take HAART. In these cases, AZT is appropriate to reduce disease transmission. Cesarean section is recommended with viral load >1000 copies/mL. Opportunistic infections require standard therapies despite the potential fetal effects. |
| Syphilis           | Fetal—congenital syphilis, fetal loss, PTD, IUGR, nonimmune hydrops                  | Primary, secondary, early latent (<1 yr)—benzathine penicillin G, 2.4 million units IM × one dose  
  Late latent (>1 yr or unknown duration) — benzathine penicillin G, 2.4 million units IM weekly × three doses  
  Neurosyphilis—aqueous penicillin G, 2–4 million units IV q4h × 10–14 days, or procaine penicillin G, 2.4 million units IM, and probenecid, 500 mg PO q6h × 10–14 days |
| Systemic lupus erythematosus (SLE) | Fetal—PTD, IUGR, fetal loss, cesarean section  
  Maternal—SLE flare, worsening of renal dysfunction, thrombocytopenia, anemia, preeclampsia, subclinical coronary vascular disease | Initiation of aspirin therapy post–16 wk for decreasing preeclampsia risk. Close monitoring of SLE nephritis via decreasing C3 and C4 levels and elevated anti-DNA antibodies, monitoring of proteinuria. Markers of disease activity via increased lupus anticoagulant levels and antiphospholipid antibody levels  
  Natural disease hiatus during pregnancy |
| Rheumatoid arthritis | Fetal—IUGR  
  Maternal—increased flare within 1 yr of pregnancy | Aspirin after 16 wk EGA  
  Azathioprine as a safer alternative to cyclophosphamide or methotrexate in first and second trimesters |
| Eating disorders (anorexia nervosa, bulimia nervosa [BN]) | Fetal—miscarriage, low birth weight, preterm birth, congenital malformations (neural tube defects)  
  Maternal—cesarean section, depression | Restoration of normal physiologic parameters (electrolyte replacement and clearance of ketosis)  
  Antidepressants for BN |
| Alcohol            | Fetal—IUGR, low birth weight, miscarriage, IUFD, fetal alcohol spectrum disorders  
  Maternal—increased risk of unintended pregnancies, alcohol withdrawal | Any gravid patient with signs of active withdrawal should be considered for inpatient management. |
| Smoking            | Fetal—miscarriage, IUFD, preterm birth, IUGR, SIDS, congenital deformities (clubfoot)  
  Maternal—decreased risk of preeclampsia | Behavioral and cognitive treatment for cessation  
  Nicotine patches in second and third trimesters appear safe in limited studies. |
| Opioids            | Fetal—IUGR, SIDS, narcotic abstinence syndrome, NICU admissions  
  Maternal—increased risk of unintended pregnancies, withdrawal, endocarditis | Close monitoring of fetal depression peripartum  
  Management of methadone maintenance to decrease risk of IV drug injection complications |

physiologic anemia, which may precipitate angina.\textsuperscript{19,20} Hypertension, thrombophilia, anemia, diabetes, advanced maternal age, multiparous state, and smoking increase the risk of pregnancy-associated AMI.\textsuperscript{19}

Approximately 13% to 25% of pregnant patients diagnosed with ACS have normal coronary arteries.\textsuperscript{20} In one study, 43% of patients diagnosed with AMI had atherosclerosis, with or without thrombus, 21% had coronary thrombus, and 16% had dissection.\textsuperscript{19} AMI with normal coronaries tends to occur during the peripartum period. Other causes such as coronary artery dissection and vasospasm are more likely to occur in otherwise normal vessels, whereas atherosclerotic disease causes most AMIs in the antepartum period. Pulmonary embolus, reflex esophagitis, biliary colic, and aortic dissection are all more common than myocardial ischemia during pregnancy and should be considered in the differential diagnosis of the pregnant patient who presents with chest pain. Initial signs and symptoms of AMI, such as chest pain and shortness of breath, are often attributed to the normal physiological changes of pregnancy.\textsuperscript{18,20,21}

The diagnosis of ACS is similar to that in nonpregnant patients, with certain exceptions. Electrocardiographic changes sometimes occur in normal pregnancies and delivery. These include T wave flattening, T wave inversion (mainly in lead III), and nonspecific ST changes during pregnancy, as well as ST depression during labor induction for cesarean section.\textsuperscript{22} As a result, an additional evaluation may be necessary. Echocardiography is useful in the correlation of suspicious electrocardiographic findings with wall motion abnormalities. The enzymatic diagnosis of myocardial infarction is unchanged, except during and immediately after delivery; the troponin level is preferred to the creatine kinase level because it rises above baseline during this time. The United Kingdom’s Saving Mother’s Lives Report has found that in gravid women who died from cardiac ischemia, care was substandard in 46% of cases. Key diagnostic and management issues include the following\textsuperscript{18,20,22}:

- Ischemic cardiac disease as a cause of symptoms should be considered.
- Asymptomatic pregnant patients with ischemic cardiac disease may have a normal electrocardiogram (ECG), so evaluation for chest pain should include serial ECGs and troponin levels.
- A normal echocardiogram does not exclude myocardial infarction (non–ST segment elevation MI).
- Cardiologists are reluctant to perform coronary angiography because of pregnancy.

Treatment of AMI during pregnancy is similar in most respects to treatment of the nonpregnant patient, with survival of the mother as the goal (see Table 179.3). Standard treatments including antiplatelet agents, nitroglycerin, and beta blockers: antithrombotic agents are considered safe during pregnancy but the decision to use them should be made jointly by emergent consultation with a cardiologist.\textsuperscript{18,21} Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, aldosterone antagonists, and statins are not advised until the postpartum period. Aspirin is the first-line antiplatelet agent. Clopidogrel and eptifibatide have been studied in case reports, with no adverse fetal outcomes, and the benefit of their use outweighs any risks.\textsuperscript{21} Heparin has long been the antithrombotic of choice for pregnant patients, although low-molecular-weight agents such as enoxaparin also do not cross the placenta and are considered efficacious and safe in pregnancy.\textsuperscript{18}

Cardiac catheterization with stenting is the treatment of choice for AMI in the pregnant patient and, with shielding, exposes the fetus to less than 1 radiation-absorbed dose (rad).\textsuperscript{18} When a catheterization laboratory is unavailable, lifesaving thrombolytic therapy should not be withheld. Although thrombolytics do not cross the placenta, there is an increased risk of maternal hemorrhage and, in the setting of AMI caused by coronary dissection, thrombolytic use can worsen the dissection.\textsuperscript{20,21} Because thrombolytic therapy precludes major surgery and epidural anesthesia in the hours to days immediately after administration, one must carefully consider whether to use these agents in pregnant women who are close to term, especially if the need for cesarean delivery is anticipated.

In the setting of peripartum AMI, labor should be conducted with continuous monitoring of the mother’s hemodynamic status and fetal well-being. Assisted vaginal delivery is preferred unless there is an indication for cesarean section. Cesarean section avoids prolonged exertion by the mother but can subject the patient to general anesthesia if the use of antithrombotic agents precludes epidural catheter placement.

### Valvular Heart Disease and Pulmonary Hypertension

**Principles.** The European Registry on Pregnancy and Heart Disease has reported that mitral stenosis and regurgitation are the most common types of valvular disease (63%), followed by aortic valve disease (23%).\textsuperscript{23,24} The ability of patients to tolerate pregnancy without significant adverse effects depends on the type and severity of the lesion. Mild to moderate lesions (New York Heart Association [NYHA] classes I and II) are often associated with good outcomes for the mother and fetus. On the other hand, mitral stenosis (beyond class I), advanced aortic stenosis, and aortic and mitral lesions associated with moderate to severe ventricular dysfunction or pulmonary hypertension, as well as mechanical prosthetic valves requiring anticoagulation, can result in significant maternal mortality and require directed therapy and expert cardiology consultation (Table 179.5).\textsuperscript{23,24}

Heart failure is the most common maternal complication in pregnancy with valvular heart disease.\textsuperscript{23,24} In the European Registry on Pregnancy and Heart Disease, hospital admissions occurred in 38% of pregnant patients with valvular heart disease. Diagnosing heart failure is challenging because women in the last months of pregnancy experience symptoms such as dyspnea on exertion,

NYHA, New York Heart Association.

paroxysmal nocturnal dyspnea, orthopnea, and pedal edema that are identical to those of heart failure. Normal B-type natriuretic peptide (BNP) levels can be used to rule out heart failure in pregnant females but, because BNP levels are higher in pregnant females, an elevated BNP level can be difficult to interpret.27

Pulmonary Hypertension. Pregnancy is poorly tolerated by patients with pulmonary hypertension because the pulmonary circulation cannot cope with the increased stroke volume and cardiac output of pregnancy, causing pulmonary pressures to rise. This causes dyspnea, heart failure, and syncope. Mortality in pregnant women with pulmonary hypertension has been reported to be as high as 30%, although a more recent study has demonstrated a mortality of 25% likely due to improvements in recognition and treatment.28 Pregnancy is contraindicated, and patients early in pregnancy should be counseled about elective pregnancy termination.29

The treatment of the pregnant patient with pulmonary hypertension focuses on diuresis and pulmonary vasodilation. Diuretics are indicated for the management of volume overload, and common diuretics—with the exception of spironolactone—are considered safe, although limited data exist regarding their effect on the fetus.29 Specific agents for treating pulmonary hypertension include endothelin receptor agonists (ERAs), phosphodiesterase inhibitors, and prostanooids. Phosphodiesterase inhibitors such as sildenafil and tadalafil, as well the prostacyclin derivatives epoprostenol and treprostinil, have not been shown to be fetotoxic in animals and are regularly used in pregnancy. ERAs such as bosentan and ambrisentan are teratogenic.

Mitral Stenosis. Mitral stenosis is the most commonly encountered valvular lesion in pregnancy and is also the most important lesion to detect in early pregnancy because it can cause maternal mortality.23,24,25 The increased resting heart rate and stroke volume in normal pregnancy increase the pressure gradient across the mitral valve and can cause symptoms of left heart failure, as well as atrial arrhythmias such as atrial fibrillation.10 The likelihood of maternal symptoms and worsening of cardiovascular status is directly related to the severity of disease. Pregnancy in women with mild mitral stenosis is generally well tolerated.

Beta blockers are the mainstay of treatment for patients with symptomatic mitral stenosis. Diuretics may also be used for patients with symptoms of heart failure10,12,23,26 (see Table 179.3). Surgical intervention is indicated for patients with refractory symptoms despite optimal medical management and in patients with pulmonary hypertension.1,2,3

Aortic and Mitral Regurgitation. Mitral valve prolapse is the most common cause of mitral regurgitation in developed countries, whereas rheumatic heart disease is the most common cause worldwide.23 In most cases, chronic regurgitation lesions are well tolerated during pregnancy and may even improve because the reduced systemic vascular resistance of pregnancy allows more forward and less regurgitant flow. In addition, this effect is aided by the increase in heart rate and shortened diastole that occur in pregnancy.23 When necessary, medical therapy consists of diuretics, digoxin, and vasodilators.

Aortic Stenosis. Symptomatic aortic stenosis during pregnancy usually occurs in the setting of a congenital bicuspid valve. Patients with mild to moderate aortic stenosis tend to have uncomplicated pregnancies; conservative management is often possible, especially if the aortic valve area is greater than 1.0 cm². Patients with symptomatic aortic stenosis may respond to bed rest or preload reduction with diuretics. Severely symptomatic patients may need percutaneous valvotomy and surgical replacement.23,24

Prosthetic Heart Valves. Pregnancy is a hypercoagulable state and leads to an increased risk of thromboembolic events, especially in patients with prosthetic valves or underlying valvular disease.23,24 Pregnant patients with prosthetic heart valves who are not anticoagulated have a maternal mortality as high as 5%, and thromboembolic events can occur in up to 24% of cases.20 Warfarin is the most effective anticoagulant in preventing maternal thromboembolic events.12 However, warfarin is considered teratogenic in the first trimester. Neither unfractionated heparin (UFH) nor low-molecular-weight heparin (LMWH) crosses the placenta and are not teratogenic. However, their use throughout pregnancy is not recommended due to the increased risk of thromboembolic events as compared to using UFH or LMWH in the first trimester, followed by warfarin for the remainder of pregnancy.12,23

Current anticoagulation recommendations in pregnant patients with prosthetic heart valves are to continue using warfarin until pregnancy has been achieved. If an international normalized ratio of 2.5 to 3.5 can be achieved with a warfarin dose less than or equal to 5 mg, warfarin may be used throughout pregnancy after a full discussion with the patient about the benefits and risks of the therapy. If a dose more than 5 mg is required, UFH or LMWH should be used in the first trimester, with warfarin being resumed for the second and third trimesters.12,23 Warfarin should again be replaced by UFH or LMWH several weeks before delivery.

**HEMATOLOGIC DISORDERS**

Anemia

Anemia is the most common medical complication of pregnancy. Recent research has indicated that anemia may be associated with maternal mortality, perinatal mortality, preterm birth, low birth weight, and small-for-gestational-age infants.23 The classic clinical presentations of anemia include pallor, fatigue, and shortness of breath.23 Most anemia, however, is asymptomatic. The hemoglobin threshold for severe anemia requiring blood transfusions is typically considered to be less than 7 g/dL for gravid patients and less than 8 g/dL for postpartum patients.23 There are several types of anemia exist, but four types predominate: dilutional anemia, iron deficiency, folate deficiency, and sickle cell hemoglobinopathy.

Dilutional Anemia

Dilutional anemia differs slightly from the other three. Where iron deficiency, folate deficiency and sickle cell hemoglobinopathy anemias are complications of pregnancy, dilutional anemia is a normal process associated with pregnancy. In preparation for blood loss at delivery, blood volume increases by nearly 50% between weeks 6 and 34. This rapid blood volume increase, accompanied by a lag in red blood cell (RBC) production, results in a dilution of hemoglobin. The result is that the threshold for anemia in gravid patients is slightly lower (11 g/dL) than in nongravid patients (12 g/dL). Pregnant patients with hemoglobin values typically considered normal in the nongravid patient have an increase in adverse outcomes such as preeclampsia, intrauterine growth retardation, and preterm birth, and the emergency clinician should consider that gravid patients with hemoglobin values of 13 to 15 g/dL have inadequate expansion of their plasma volume.32

Iron Deficiency Anemia

Iron deficiency anemia is common, occurring in approximately 20% to 25% of pregnancies in industrialized countries.32 The risks of adverse pregnancy outcomes (see Table 179.3) have been noted
to relate to the severity of the anemia. Studies have indicated a higher risk of preterm birth and low birth weight in patients with mild to moderate anemia, whereas severe anemia (<6 to 7 g/dL or 60–70 g/L) is associated with increased fetal mortality, abnormal fetal oxygenation, premature rupture of membranes, gestational hypertension, and reduced volume of amniotic fluid. The diagnosis is made most accurately in the very early stages of pregnancy because serum ferritin, the most sensitive and specific (and preferred) test, is affected by the dilution effect of increased plasma volume occurring later in pregnancy. Other supporting laboratory evidence includes low plasma iron levels, increased free erythrocyte protoporphyrin, and elevated total iron-binding capacity.

The ACOG has developed guidelines for the management of iron deficiency anemia. Patients with an uncomplicated physiologic anemia who are not iron-deficient can be expected to have good obstetric outcomes without therapy and do not require treatment. Patients presenting with iron deficiency anemia should be treated with non–enteric-coated supplemental iron. The use of prophylactic supplementation in women with normal hemoglobin levels (>11 g/dL [110 g/L]) and normal iron stores (ferritin > 20 mg/dL [20 µg/L]) to prevent anemia in late pregnancy is controversial. However, recent studies and meta-analyses have demonstrated that prenatal iron supplementation significantly reduces the risk of anemia at term by 70% and the risk of iron deficiency anemia at term by 57% to 66%. The dose of iron recommended by the World Health Organization (WHO) is 60 mg/day, but the Institute of Medicine has suggested an upper limit of 45 mg/day due to the gastrointestinal side effects of higher doses.

Folate Deficiency

Folate is critical to several intracellular processes associated with cell growth. However, due to the 5- to 10-fold increase in folate requirements during pregnancy, gravid patients are at risk for folate deficiency. Folate deficiency is one of a number of causes of megaloblastic anemia, which is the second most common anemia. The incidence of folate deficiency in pregnancy is low in developed countries but remains higher in other populations. The risk for development of folate deficiency is increased in patients with multiple gestations, short interpregnancy intervals, preexisting malnutrition, hyperemesis gravidarum, malabsorption syndromes, alcoholism, use of certain antiepileptic drugs, and diets lacking green leafy vegetables and animal protein. Low maternal folate stores have, most importantly, been linked to increased risk of neural tube defects, as well as increased risk of placental abruption, preterm birth and low birth weight, preeclampsia, and spontaneous abortion. As is the case for iron deficiency, effects on the fetus depend on the degree of anemia. Iron deficiency and folate deficiency anemias often coexist, making the peripheral blood smear difficult to interpret. In cases of suspected folate deficiency, the measurement of serum and RBC folate levels is indicated. However, the serum folate level is noted to exhibit a rapid response to folate intake, and low levels may normalize within days after a folate-rich meal. The serum folate level is also affected by the hemodilution of pregnancy. Oral folate supplementation with 0.4 mg daily is routinely recommended for all women before conception, and 0.4 to 0.8 mg is recommended during pregnancy as the requirement for this micronutrient increases during gestation. The ACOG recommends 1.0 mg for those women who have a known pregnancy-related folate deficiency. Women at higher risk for neural tube defects (eg, neural tube defects in prior pregnancy) are advised to take much higher doses of folate, 4 mg daily, under close supervision of their obstetrician. ACOG advises continuing oral folate supplementation throughout the second and third trimesters.

Sickle Cell Anemia

Sickle cell disease (SCD) is one of the major sources of maternal and fetal complications in the United States. The details of the pathophysiologic mechanism and genetics of SCD are discussed in Chapter 112, but it is useful to review the most common phenotypes that affect pregnancy. The sickle gene can be homozygous (hemoglobin SS or SCD), and this form of the disease is responsible for most pregnancy complications. The sickle gene can also be heterozygous with normal hemoglobin A (sickle cell trait, or hemoglobin SA), in which case symptoms are rare, except under extreme environmental conditions. Hemoglobin S can also be heterozygous with a large number of abnormal hemoglobins, such as hemoglobin C, several variants of thalassemia, and other rare hemoglobin variants; each variant has its own complication profile. Of these, the most relevant in terms of pregnancy complications is hemoglobin SC.

Patients with SCD are subject to many chronic medical problems secondary to a variety of pathophysiologic mechanisms, including sickling of RBCs, anemia, immunosuppression caused by autosplenectomy, and repeated transfusion. Median life expectancy is in the fifth decade for both genders affected by SCD, and female fertility is generally unaffected, so it is likely that the emergency clinician will encounter pregnant patients with the disease. Maternal complications are common in patients with SCD; these include preterm labor, eclampsia, premature rupture of membranes, maternal infections, more frequent pain crises, thrombosis, preeclampsia, and increased need for cesarean delivery. Despite these complications, the maternal mortality rate is less than 1% with current treatment. SCD also results in adverse effects on the fetus (see Table 179.3). Placental infarction and insufficiency are common, and the incidence of premature labor, small-for-gestational-age infants, and low-birth-weight infants is significantly increased in SCD pregnancies compared with normal controls. The reported perinatal mortality rate varies but is low in the setting of appropriate maternal and neonatal care.

Vasoocclusive crises and anemia occur more often in pregnancy and are the most common complications of SCD in pregnancy. There have been no good randomized trials studying the management of SCD during pregnancy, so recommended treatment is similar to that for the nonpregnant patient (see Table 179.3). Hydroxyurea is not recommended for use in pregnancy because of potential teratogenicity, and nonsteroidal antiinflammatory drugs (NSAIDs) are avoided after 30 weeks of gestation. General anesthesia can result in an increase in postpartum sickling complications, so regional anesthesia is preferred in the case of cesarean delivery. The use of supplemental iron and transfusion is controversial because of the potential for iron overload, alloimmunization, volume overload, and hyperviscosity syndrome. Therapeutic transfusions should be given to patients with severe disease manifestations such as symptomatic anemia, cardiopulmonary instability, acute chest syndrome, intrapartum hemorrhage, and preeclampsia. In general, the goal with transfusion or exchange transfusion is to lower the percentage of hemoglobin S to 40% and achieve hemoglobin values of approximately 10 g/dL (110 g/L). Transfusions aimed solely at secondary prevention of adverse events such as pain crises have not shown improvement in pregnancy outcomes.

NEUROLOGIC DISORDERS

Epilepsy

Epilepsy is the most common neurologic complication of pregnancy but remains relatively rare, affecting less than 1% of all
gestations. Epilepsy refers to a broad spectrum of seizure disorders that range from relatively benign and infrequent seizures to a disabling condition with daily, poorly controlled generalized convulsions; therefore, care is individualized. The treatment of epilepsy during pregnancy entails balancing the risk of increased frequency and duration of seizures to the mother and fetus against the teratogenic risks of antiepileptic drugs (AEDs).

The effect of pregnancy on epilepsy is variable. Most epileptic patients (50%–76%) experience no change in their seizure frequency, whereas approximately 15% experience more frequent seizures.6 Delivery and the first 24 hours postpartum are the most likely times for a seizure to occur, with a ninefold greater incidence of seizure than during pregnancy in general. A decrease in plasma drug concentrations is expected with certain AEDs, such as phenytoin, lamotrigine, oxcarbazepine, and levetiracetam.50 Many authors have recommended that maternal plasma drug levels should be monitored and compared to prepregnancy levels.49,50 Antiepileptic medications also increase the clearance of medications, including oral contraceptives, making unintentional pregnancy a possibility.

Gravid patients with epilepsy may be at increased risk for cesarean section, postpartum hemorrhage, and other adverse outcomes (see Table 179.3).33 Patients who have nonconvulsive seizure disorders or who are seizure-free for a sufficient period of time before conception are candidates for nonpharmacologic observation because the risk of treatment with AEDs can outweigh the benefit.69 This decision should be deferred to the patient’s primary physician or neurologist. However, there are significant obstetric complications related to prolonged seizure activity, and long-term treatment with an AED for most patients with seizures is warranted (see Table 179.3).

The primary complication of AED use in pregnancy is congenital malformations. Of primary concern is the risk for neural tube defects, facial clefts, cardiac anomalies, and cognitive defects with the older generation agents (eg, valproate, carbamazepine, phenytoin) and the newer generation agents (eg, lamotrigine, topiramate, levetiracetam). There is a two- to three-fold increase in the incidence of serious congenital malformations in offspring of epileptic mothers taking these agents. The risk is greatest with valproate and is also increased with AED polypharmacy and increased dose of individual agents.65-68 Of all the older agents, carbamazepine appears to be the safest for use as monotherapy.65,66 Recent studies have looked at the risk of major congenital malformations of the newer AEDs and have found that in monotherapy with lamotrigine or levetiracetam, the risks are lower than those in the older agents.49,53,55 Specifically, the United Kingdom and Ireland Epilepsy and Pregnancy Registry has found a rate of major congenital malformations of 0.7% for women receiving levetiracetam monotherapy; the North American AED Pregnancy Registry found a rate of 2.4%.52,54 Both these rates are significantly below those of other AEDs.

When compared to the older AEDs, levetiracetam performed as well at controlling seizures when used in monotherapy. However, lamotrigine and topiramate, when used in monotherapy, showed worse seizure control.76 Because phenytoin, carbamazepine, valproate, and possibly other AEDs interfere with folate metabolism, oral supplementation with at least 0.4 mg/day is recommended for all women of childbearing age taking these drugs to help prevent congenital malformations such as neural tube defects. Enzyme-inducing AEDs such as carbamazepine, phenytoin, and phenobarbital have been reported to cause neonatal vitamin K deficiency and neonatal hemorrhage, but the American Academy of Neurology and American Epilepsy Society have noted that there is inadequate evidence to determine a definitive relationship.

Any potential cause of seizure, including eclampsia, may result in status epilepticus. Despite this, status epilepticus in pregnancy is relatively rare, and limited data are available about its occurrence and therapy. Observations from the European Epilepsy Pregnancy Registry have noted that status epilepticus may occur at any time during gestation and even at delivery. It may also occur in patients who have been seizure-free throughout pregnancy, and no specific risk factors for its occurrence have been identified. Older reports noted a high fetal and maternal mortality, but recent data support a much lower complication rate.

The risk of untreated status epilepticus to the mother and fetus clearly outweighs the potential for adverse teratogenic effects, and standard resuscitative measures, as well as drug therapy, are indicated. Continuous fetal monitoring should be instituted as soon as possible to observe for signs of fetal hypoxia, and the mother should be positioned in the left lateral decubitus position to avoid the supine hypotensive syndrome.39

Multiple Sclerosis

Multiple sclerosis (MS) affects approximately 400,000 Americans and is twice as common in women as in men. The peak age at onset is 20 to 35 years, which overlaps peak childbearing years. The disease is characterized by intermittent episodes of central nervous system (CNS) demyelination, with consequent neurologic impairment that follows a relapsing-remitting course. Progressive neurologic deficits and permanent disability develop in certain patients.

The impact of pregnancy on the course of MS has been closely studied in various cohorts and, as in other autoimmune diseases, the frequency and severity of exacerbations of MS improve because of the immunosuppressant effects of pregnancy. This effect is most pronounced in the third trimester. During the 3 months after delivery, the rate of relapse increases and then returns to the prepregnancy baseline.56-57 Relapses are more likely in MS patients with higher disability at the time of pregnancy onset. However, it does not seem that postpartum relapses are related to the duration of disease or total number of relapses before conception.

MS patients with disease exacerbation are often treated with immunomodulators such as intravenous immune globulin (IVIG), corticosteroids, glatiramer acetate, and interferon beta. Small studies in gravid patients have shown that the use of IVIG during pregnancy and in the postpartum period is safe and may decrease the relapse rate.58-60 Likewise, the use of intermittent steroids in the postpartum period may decrease the likelihood of disease relapse. Although the evidence is not conclusive, it is currently not recommended to treat MS exacerbations during pregnancy with interferon beta or glatiramer acetate based on evidence that they may cause adverse fetal effects.68,69

Spinal Cord Injury

Because spinal cord injury (SCI) occurs mainly in young people and usually does not impair fertility, there is a relatively large population of paraplegic and quadriplegic patients who become pregnant.60 Pregnant women with SCI are twice as likely to have preterm labor and are at increased risk of having a low-birthweight infant.61 Although many of these pregnancies are uneventful, these patients are at risk for certain complications.

The hypercoagulable state of pregnancy, combined with chronic immobilization, results in an increased incidence of thromboembolic disease, with the incidence of deep vein thrombosis (DVT) reported as high as 8% in pregnant women with SCI.60 The incidence of urinary tract infection is also markedly increased as a result of neurogenic complications and the need for catheterization.60 Infections are even more likely during pregnancy and may progress to pyelonephritis, with the subsequent increased risk of fetal loss, prematurity, and maternal sepsis.
Autonomic dysreflexia is the most serious complication of SCI and occurs in up to 85% of women with high lesions (above T5-T6); it occurs with increased frequency during pregnancy. Autonomic dysreflexia is manifested as severe paroxysmal hypertension, headache, tachycardia, diaphoresis, piloerection, mydriasis, and nasal congestion. It is often precipitated by afferent stimuli from the hollow viscus such as the bladder, bowel, or uterus. Symptoms of autonomic dysreflexia often occur with uterine contractions during labor. However, labor may be difficult to detect because patients with spinal cord lesions below T10 to T12 have an intact uterine nerve supply and will experience labor pains; however, with lesions above T10, labor may be imperceptible or experienced as only mild abdominal discomfort. Pregnant patients with SCI with symptoms of autonomic dysreflexia should be assessed for cervical dilation and have uterine contractions monitored. ED treatment is directed at the restoration of normal blood pressure with standard agents. Definitive therapy is with regional anesthesia. Spinal anesthesia and epidural anesthesia obliterate and prevent this response and should be used as soon as possible during labor for all women with SCI. Finally, it can be difficult to differentiate between the symptoms of autonomic dysreflexia and preeclampsia. In autonomic dysreflexia, symptoms such as hypertension will resolve once the stimuli to the skin or hollow viscus have been relieved; in preeclampsia, the symptoms and laboratory abnormalities are more likely to persist.60

Myasthenia Gravis

Myasthenia gravis is a rare disorder in which autoimmune destruction of the postsynaptic cholinergic receptor results in profound muscle fatigability. The effect of pregnancy and postpartum state on myasthenia gravis is unpredictable in the individual patient, but overall, approximately 25% to 40% of patients experience exacerbation of disease, with the remainder having improvement or no change in disease severity.61–64 Disease exacerbations are most likely in the first trimester or puerperium, with improvement in symptoms often seen in the second and third trimesters due to the hormone-mediated immunosuppression of pregnancy.61–64 Because of weight gain, anemia, and other physiologic adjustments of pregnancy that may result in fatigue, the distinction between normal pregnancy symptoms and myasthenia may be difficult. Also, these changes, along with the nausea and vomiting of normal pregnancy, may result in a need to adjust medication dosage requirements.60

Most deliveries are accomplished vaginally without complications in adequately treated patients; assisted and surgical delivery in these women is indicated mainly for obstetric reasons rather than for specific myasthenia-related care.62 Up to 30% of neonates born to mothers with myasthenia gravis have a transient neonatal myasthenia syndrome through the placental transport of acetylcholine receptor antibodies.63–64 There is no correlation between the severity of maternal disease and occurrence of neonatal myasthenia.63 The onset of neonatal myasthenia is typically within the first hours of life but may be delayed by a period of days. Manifestations include poor feeding and suck, diminished reflexes, hypotonia, and bulbar and respiratory muscle weakness. As in adults, the symptoms respond to cholinesterase inhibitors, but treatment should be carried out in an intensive care unit setting.64

Myasthenia crises during pregnancy present with typical symptoms of painless fluctuating weakness of skeletal muscles. With extracranial muscle involvement, diplopia and ptosis are the most common early symptoms.65 When exacerbations do occur, treatment is no different from the treatment of nonpregnant patients (see Table 179.3). Acetylcholine esterase inhibitors, corticosteroids, azathioprine, IVIG, and plasmapheresis are all considered safe for the mother and fetus.64 Assessment of pulse oximetry, forced vital capacity, and arterial blood gas parameters will guide respiratory therapy. For patients presenting with weakness, an edrophonium (Tensilon) challenge test to distinguish myasthenia from cholinergic crisis is appropriate after the initiation of appropriate ventilatory support. Standard medical treatment is continued during labor and delivery to maximize motor strength. Epidural anesthesia is also recommended to reduce pain and fatigue. The emergency clinician should be aware that 30% of patients experience an exacerbation during the postpartum period as the protective immunosuppressant effect of pregnancy dissipates.61,64

RENAL DISORDERS

Chronic kidney disease (CKD) can be silent well into its disease course and is more difficult to diagnose in pregnancy because of expected decreased blood urea nitrogen (BUN) and creatinine levels during pregnancy. For women with known renal disease, including end-stage renal disease, on hemodialysis, pregnancy rates are 1% to 7%. For those post–renal transplantation, fertility rates return to prerefnal failure levels within 1 to 6 months post-transplantation, so pregnancy is not an uncommon finding in posttransplantation women of childbearing age.

CKD in and of itself is an independent risk factor for maternal and fetal complications. The degree of underlying renal dysfunction is a strong determinant of morbidity associated with pregnancy. Patients with moderate to severe renal dysfunction have a much higher risk of further decline in renal function, as well as adverse obstetric outcomes, including preeclampsia, placental abruption, fetal loss, preterm delivery, low birth weight, polyhydramnios, and increased need for cesarean section and neonatal intensive care.65–68 Despite this, 80% of pregnancies with a maternal BUN level higher than 60 mg/dL ended in the delivery of live births. Worsening of underlying renal function is more likely in patients with a decreased glomerular filtration rate who also have associated proteinuria or hypertension. Because worsening renal function is manifested by hypertension and proteinuria, differentiation from preeclampsia can be difficult. In this setting, it is best to treat the patient for presumed preeclampsia, with the caveat that magnesium administration should be performed judiciously on the basis of serum magnesium levels.

Pregnant women with chronic renal failure require aggressive and timely management to optimize their chances for a successful gestation without causing further deterioration in renal function. One of the most successful tenets of CKD management in pregnancy is close control of blood pressure and monitoring for proteinuria. Treatment regimens are the same as those outlined earlier (see “Chronic Hypertension and Hypertensive Emergencies”).

Evidence of renal function deterioration or the development or exacerbation of hypertension warrants admission for specialized inpatient care. Hemodialysis is indicated for creatinine levels above 3.5 to 5 mg/dL (266.9–381.3 µmol/L). Pregnancy in women who are already dialysis-dependent has been associated with poor outcomes, and pregnancy has previously been discouraged in these patients. However, studies including small numbers of women have noted live birth rates approaching 60% to 85% when mothers receive specialized prenatal care.65,66 Such care includes correction of anemia, appropriate antihypertensive therapy, and more aggressive dialysis with more frequent or prolonged sessions.60

METABOLIC AND ENDOCRINE DISORDERS

Diabetes

Three types of diabetes affect pregnant patients—type 1, or insulin-dependent diabetes mellitus (IDDM); type 2, or
non–insulin-dependent diabetes mellitus (NIDDM); and gestational diabetes mellitus (GDM). Although risk factors for GDM can be identified preconception, it is not classified as a preexisting medical condition and will not be considered in this discussion. However, the considerations for glycemic control in GDM are the same as those for IDDM and NIDDM. Although NIDDM is sometimes considered a more benign form of disease, the risk of pregnancy complications and fetal malformations is, at best, the same for NIDDM and IDDM. Some studies have shown that complications, maternal and fetal, are actually greater for NIDDM. 67

This represents a distinct medical challenge, given the ever-increasing prevalence of NIDDM and the generally lower rates of glycemic control and preconception planning in this patient population. In general, maternal and fetal complications relate to inadequate glycemic control and to the presence of vascular complications or severe renal insufficiency more than to the type of diabetes. Glycemic control is incrementally more challenging during pregnancy because of complexities in glucose regulation precipitated by hormonal changes. Specifically, in early pregnancy and again in the peripartum period, hyperglycemia is common and is caused by increased insulin resistance, even in IDDM patients. Obesity and preexisting insulin resistance in NIDDM can further complicate efforts of glucose control. 68 Ideally, hemoglobin A1c (HbA1c) values should not be higher than 6% (see Table 179.3); the best outcomes occur when tight glycemic control is achieved for at least 4 months preconception. 69 Experts have recommended that NIDDM patients taking oral agents be transitioned to insulin during pregnancy. 70 The predisposition to develop diabetic ketoacidosis (DKA) throughout pregnancy has been well documented; this is attributable to hormonal changes. An increased risk of significant hypoglycemic episodes stems from attempts at very tight glucose regulation, but is also caused by diminished glucagon response to hypoglycemia, emesis, and increased metabolic demands of the placenta and growing fetus.

**Maternal Complications**

The effects of pregnancy on underlying diabetes vary by organ system. The data are limited, but pregnancy is not advised for diabetic patients with significant coronary artery disease because of the cardiovascular demands of pregnancy and high mortality of AMI during pregnancy. Given the likelihood of silent ischemic events in the diabetic population, atypical or vague presentations of angina or MI, including new-onset congestive heart failure should be carefully evaluated in those with preexisting known coronary artery disease, but also in any diabetic mother. 71

Patients with diabetic nephropathy are at increased risk for preeclampsia and the subsequent requirement for preterm delivery. Following progression of nephropathy closely in conjunction with aggressive blood pressure control and optimizing protein intake are strongly recommended. Retinopathy worsens acutely in 77% of pregnancies, and those at greatest risk for this are patients with high HbA1c levels, hypertension, nephropathy, and active nonproliferative or proliferative retinopathy. Laser therapy of preexisting retinopathy is recommended before conception, as well as for pregnant patients with severe disease. 71-73 Patients with known proliferative retinopathy should be counseled to avoid excessive, aggressive Valsalva maneuvers during labor to minimize the risk of retinal hemorrhages. 74 Autonomic neuropathy does not accelerate during pregnancy, with the exception of a possible increase in symptomatic severity of gastroparesis.

DKA occurs in up to 9% of diabetic patients during pregnancy and may be the initial presentation of diabetes. DKA is usually seen in patients with IDDM but also complicates pregnancies in women with NIDDM and GDM. Common precipitating events include the typical factors seen in nonpregnant patients, such as insulin noncompliance and infection. Other pregnancy-specific factors are increased insulin resistance, hyperemesis, use of beta-mimetic medications for tocolysis, and use of corticosteroids to hasten fetal lung maturity. The serum pH may be deceptively normal in a pregnant patient with DKA because the initial pH tends to be higher in pregnancy as a result of physiologic hyperventilation. In addition, the serum glucose concentration may be normal or only moderately elevated. Therefore, screening for DKA is indicated in gravid diabetics with nausea, vomiting, malaise, or headache in those with persistent hyperglycemia. Maternal mortality is rare in those with appropriately treated DKA. Fetal mortality rates are relatively high, ranging from 10% to 35%. 74

**Fetal Complications**

Diabetes has many deleterious effects on the fetus (see Table 179.1). The risk of congenital anomalies in infants of diabetic mothers (IDMs) is as high as 10%. 74 The rate of congenital malformations in patients with prepregnancy diabetes is increased threefold or fourfold compared with the nondiabetic population, with anomalies being more likely in pregnant women with poor glycemic control. 66,75,76 Macrosomia is the most likely factor leading to the need for cesarean section and has been associated with shoulder dystocia. Conversely, preeclampsia and placental infarction secondary to vascular disease may result in impaired fetal development and stillbirth. 76 Diabetic patients are also at increased risk of spontaneous preterm delivery and labor-induced preterm deliveries. 77 Neonatal complications seen at increased rates in IDMs include transient tachypnea of the newborn, neonatal hypoglycemia, hypocalcemia in the peripartum period, hyperbilirubinemia, polycythemia, cardiomyopathy, and respiratory distress as a result of fetal hyperinsulinemia.

**Management**

Early management of diabetes in pregnancy in the ED requires the careful management of hyperglycemia or hypoglycemia because congenital abnormalities can occur in the first trimester. Treatment of NIDDM and IDDM requires individualized and carefully adjusted insulin administration, with the goal of maintaining strict glycemic control while avoiding hypoglycemia. Treatment of DKA in pregnancy generally follows the same principles as those in nonpregnant patients, except that fluid resuscitation and insulin therapy should be maintained in the presence of normoglycemia until bicarbonate levels return to normal, indicating that any lagging acidemia has cleared. Fetal viability and well-being should be assessed in all cases of maternal DKA.

The timing and mode of delivery depend on whether obstetric or maternal complications exist. In the absence of suspected problems, vaginal delivery at term is recommended. Elective delivery is indicated in the setting of poor metabolic control, significant diabetic complications, and fetal macrosomia with suspected birth weight more than 4500 g. 78

**OBESITY**

It is well documented that the incidence of obesity is increasing. 77 Obesity has been found to be an independent risk factor for poor predictors of pregnancy outcome, even without the comorbid conditions of diabetes, vascular disease, or hypertension. 79 Maternal risks include an increased incidence of gestational weight gain and increased risk of postterm delivery, preeclampsia, and inadequate contraction patterns in labor, leading to failure to progress. This is thought to be caused by an independent influence of obesity on myometrial activity. 79 The increased risk of undergoing
cesarean section is 3.2-fold of that seen in the nonobese population,\(^7\) and postsurgical complications of hematoma, seroma, abscess formation, and wound dehiscence all increase in obese postpartum, cesarean section mothers.\(^2\) Meta-analysis has shown obesity to be an independent risk factor for infant death and neonatal asthma; this risk is proportional to increased body mass index (BMI).\(^2\) Obesity has not been associated with increased rates of shoulder dystocia, congenital malformations, or low 5-minute Apgar scores, however.\(^5\) The BMI does not appear to be correlated with postpartum hemorrhage requiring intervention, severe maternal morbidity or maternal mortality, or spontaneous preterm delivery before 32 weeks of gestation.\(^7\)

**THYROID DISORDERS**

The peak incidence of thyroid disease is in women of childbearing age. Hypoactivity and hyperactivity of the thyroid gland lead to obstetric complications and warrant specific therapy.

**Hyperthyroidism**

The most common cause of hyperthyroidism is Graves' disease, in which autoimmune thyroid-stimulating immunoglobulin results in increased production and release of thyroid hormone. Because the symptoms of hyperthyroidism resemble the physiologic changes expected during pregnancy in many respects, the diagnosis may not be immediately evident. Patients with Graves' disease have disease-specific findings, including a diffusely enlarged, soft, mildly tender thyroid gland, exophthalmos, and dermopathy. Other symptoms, such as dyspnea, heat intolerance, hyperemesis, tachycardia, palpitations, systolic flow murmurs, increased appetite, and fatigue, are common to both conditions. Therefore, clinically differentiating Graves' disease from non–Graves'-associated hyperthyroidism can be difficult. In cases of suspected hyperthyroidism, thyroid function studies and antibody assays are indicated and will confirm the presence of disease.

There are several obstetric concerns for the mother and fetus in the setting of untreated clinical hyperthyroidism (see Table 179.3). Thyroid storm is the most serious manifestation of the disease. It may be precipitated by stressors such as infection and delivery; it is manifested by fever, dysrhythmias, myocardial dysfunction, and circulatory collapse. The most helpful differentiating symptoms between thyrotoxicosis and thyroid storm is markedly altered mental status in the presence of thyroid storm. Untreated, mortality approaches 100%, but prompt recognition and aggressive therapy have lowered mortality to 20% to 30%.\(^3\) In addition to the more general complications stemming from thyroid hormone excess, early (spontaneous abortion) and late (stillbirth) fetal loss are more common in hyperthyroid patients than in the general population.\(^3\) Graves' disease places the fetus at risk for autoimmune-mediated thyroid dysfunction through placental transfer of maternal thyroid-stimulating immunoglobulins. Up to 20% of neonates of mothers with Graves' disease and positive thyroid-stimulating immunoglobulin values have transient hyperthyroidism lasting 3 to 12 weeks.\(^3\) The condition gradually clears as maternal antibodies are metabolized. Manifestations are potentially severe and include irritability, tachycardia, goiter, cardiomegaly, congestive heart failure, premature cranio-synostosis, low birth weight, and failure to thrive.\(^3\)

The mainstay of treatment of hyperthyroidism (see Table 179.3) consists of antithyroid drugs. Propylthiouracil has been recommended as being preferred to methimazole because of an increased potential for adverse congenital drug effects from methimazole.\(^7\) Most patients respond to pharmacologic manipulation, although thyroidectomy may be considered in severe cases in which patients cannot tolerate antithyroid medication or in the setting of medication failure. Use of iodine-131 radionuclide to ablate the maternal thyroid is contraindicated because it will also destroy the fetal thyroid gland.

Additional therapy with beta blockade to mitigate the hemodynamic effects of sympathetic stimulation may be required in certain cases pending adequate disease control with antithyroid medications. Iodide is considered class D in pregnancy because of fetal thyroid sensitivity to the medication; its use should be reserved for severe cases, with duration of therapy limited to days. As with other autoimmune conditions, transient improvement of Graves' disease during pregnancy is common, with rebound and clinical deterioration occurring in most patients after delivery.

**Hypothyroidism**

The most common cause of hypothyroidism worldwide is iodide deficiency. In iodine-replete areas, the most common cause is post autoimmune thyroiditis, such as Hashimoto's thyroiditis. Overt hypothyroidism is often associated with infertility, so most cases seen during pregnancy are less severe. Subclinical disease forms can also be seen or may occur in patients already undergoing levothyroxine therapy for known disease. Undiagnosed subclinical hypothyroidism may become clinically apparent as the metabolic demands of pregnancy unmask deficient thyroid hormone levels. When signs and symptoms do occur, they are generally the same as those in the nonpregnant state. Myxedema coma is extremely rare but should be considered along with other causes of coma in a pregnant patient. As with hyperthyroidism, there is an increased incidence of adverse maternal and fetal effects in women with clinical hypothyroidism (see Table 179.3).\(^8\)

Most patients who are already undergoing treatment for hypothyroidism will require an increased dosage of levothyroxine during pregnancy, especially during the first trimester, in which average increases are from 20% to 30%.\(^9\) Approximately 3% to 5% of women of childbearing age have subclinical hypothyroidism, as defined by an elevated thyroid-stimulating hormone (TSH) level and normal thyroxine (T\(_4\)) level. It has been noted that clinical and subclinical hypothyroidism result in adverse perinatal outcomes and adverse neurologic outcomes for affected infants. Compared with euthyroid status, subclinical hypothyroid pregnancy is associated with higher rates of gestational hypertension, premature rupture of membranes, intrauterine growth restriction (IUGR), and low-birth-weight infants.\(^3\)

**SYSTEMIC INFECTIONS**

**Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome**

Human immunodeficiency virus (HIV) infection is one of the leading health problems in pregnancy. In 2008, 25% of reported cases of HIV infection and acquired immunodeficiency syndrome (AIDS) in the United States were in women, with a significant percentage being in women of childbearing age.\(^3\) Estimates of the seroprevalence of HIV infection in pregnant women vary on a regional basis. In the United States, the overall prevalence and number of perinatally infected infants are low but also vary according to the population, with increased rates seen in the southern states and in black and Hispanic populations.\(^5\) Worldwide, vertical transmission of HIV remains a significant problem.

The mechanism of vertical transmission is multifactorial. Most cases are thought to occur during delivery through exposure to maternal blood and secretions; other infants are likely to be infected in uterus or through breast-feeding. Various factors influence the rate of transmission. The most important is maternal viral load, although infection can occur even with a low maternal viral load.\(^9\) Other contributing factors for transmission include inadequate prenatal care, vaginal infections, injection drug use,
premature delivery, low birth weight, and prolonged rupture of membranes.92,94 Vertical transmission of HIV in the United States and other developed countries has declined significantly since its peak in the early 1990s because of the implementation of a number of interventions, including routine voluntary testing, highly active antiretroviral therapy (HAART), use of elective cesarean section, and avoidance of breast-feeding. However, vertical transmission remains a concern in women without adequate prenatal care and is a global concern. It is estimated that perinatal infection occurs in approximately 20% of deliveries if the mother is untreated, whereas the interventions noted have reduced this rate to less than 1%. Because of this beneficial effect, it is recommended that all pregnant women undergo screening for HIV. Rapid HIV screening is recommended for women in labor whose HIV status is unknown.92,95

Treatment of the pregnant patient with HIV infection includes appropriate HAART and standard therapy for opportunistic infections (see Table 179.3).96,97 There are limited data on specific therapy for opportunistic infections during pregnancy, but the emergency clinician should take into account the fact that medication clearance may be affected by various pregnancy-related changes, including increased renal clearance, dilutional anemia, and fetal metabolism of medications.98

Optimal therapy to prevent vertical transmission includes three stages—antepartum administration of HAART, intrapartum intravenous zidovudine dosing, and treatment of the infant with 4 to 6 weeks of zidovudine.99 The specific HAART regimen to follow depends on a number of variables. In patients who are already taking HAART with good disease control (viral load <1000 copies/mL) at the time of pregnancy diagnosis, the current medication regimen should be continued. Efavirenz (EFV) has teratogenic risks, with neural tube defect abnormalities prior to 6 weeks’ gestation, so HIV-positive women planning to become pregnant should have this regimen changed. If a woman previously on EFV becomes pregnant, current recommendations are to continue the therapy, because most pregnancies are not diagnosed prior to 6 weeks, when the potential teratogenic effects of the medication have already been sustained.92 Women who have never received any form of antiretroviral therapy are started on a standard multidrug HAART regimen that avoids the use of EFV in the first trimester. Delayed initiation of HAART until the second trimester may be considered in women if the only goal of therapy is to prevent mother to child transmission (maternal viral load <1000 copies/mL).92,99 In HIV-infected mothers without prenatal care, intrapartum HAART followed by postexposure zidovudine treatment of the infant reduces the likelihood of infection but is less effective than the recommended three-stage regimen.92,100 Elective cesarean section is recommended in mothers with a viral load greater than 1000 copies/mL.92 It is reasonable to present cesarean delivery as an option for patients with lower viral loads, although the benefit for these lower risk mothers is uncertain, and the risk of mother to child transmission by vaginal delivery is very low when mothers have received effective HAART.92,100
